

# The Macroeconomic Consequences of Family Policies\*

Anson Zhou<sup>†</sup>

September 19, 2022

## Abstract

This paper studies the macroeconomic consequences of family policies in a heterogeneous-agent overlapping generations model featuring the quantity-quality trade-off, a multi-period demographic structure, and childcare choices. I calibrate the model to U.S. data and validate the fertility elasticities using design-based evidence. I find that cash rewards for childbirth raise fertility at the expense of human capital and intergenerational mobility. This is because parents optimally reduce child investments when they increase fertility, and such effects are larger among low-income households. Interestingly, average welfare rises in the long run as the old-age dependency ratio drops, requiring lower taxes to sustain retirement benefits. Compared with cash rewards, in-kind benefits are less cost-effective in raising fertility but have other advantages, such as encouraging labor supply and improving intergenerational mobility.

# 1 Introduction

Designed to promote and enhance family formation, reproduction, and child-rearing, family policies have long been a top priority in many developed economies. Since the 1980s, government expenditures on family policies have been growing steadily among OECD countries, exceeding 2% of GDP on average. Such expenditures include both cash transfers (e.g., baby bonuses and child tax benefits) and in-kind benefits (e.g., subsidized childcare, public pre-K).

Family policies are important for four main reasons. First, they are the key policy instruments to address population aging, which poses a threat to economic growth (Jones, 2020) and the sustainability of the public pension system (Bongaarts, 2004). Second, countries use family policies to redistribute resources to families with children in order to reduce inequality. Third, it is widely believed that family policies could improve children’s outcomes and boost social mobility through relaxing parents’ borrowing constraints.<sup>1</sup> Fourth, family policies can be used to address potential inefficiencies associated with childbearing and child-rearing decisions as parents may not fully internalize the effect of an additional child on the economy (Schoonbroodt and Tertilt, 2014).

Despite the importance and wide implementation of family policies, little is known about their macroeconomic implications on fertility, human capital, intergenerational mobility, and welfare. Such evaluations are difficult for three primary reasons. First, family policies affect various choice margins, e.g., fertility and child human capital, that are deeply intertwined. In particular, as I discuss in the paper, assessing the aggregate human capital effects requires taking heterogeneous fertility responses into account. Second, family policies induce general equilibrium effects by altering demographic structure, tax rates, and prices. Third, policy effects change over time because age and human capital distributions evolve gradually as generations progress through their life cycles.

In this paper, I develop a unified framework to study family policies. The proposed model features four ingredients that are important for analyzing family policies: endogenous fertility and child investments, heterogeneity across parents, a multi-period life cycle with pay-as-you-go (PAYG) pension system, and childcare choices. Including these ingredients allows me to study several key mechanisms of family policies.

First, households in the model choose both the quantity and quality of children. From a policy perspective, both the quantity and quality margins are important because they correspond to the two main goals of family policies – raising fertility and improving children’s outcomes, respectively. Moreover, the two margins are closely linked by the *quantity-quality trade-off* à la Becker and Lewis (1973) where higher quantity raises the marginal costs of quality and may lead to unintended consequences from the policymakers’ point of view.

Second, heterogeneities across parents affect the consequences of family policies through *com-*

<sup>1</sup>For instance, see The White House (2021), Schanzenbach et al. (2021), and Pulliam and Reeves (2021).

*position effects*. As we see in the model and data, parents respond differently in their fertility and child quality decisions to the same policy. Some parents increase fertility more than others, meaning that their children comprise a larger share of the population in the future. Because parents and children tend to have similar traits (e.g., human capital) due to intergenerational linkages, aggregate variables depend more on the traits of parents with stronger fertility responses. Therefore, policy effects on the aggregate human capital differs greatly from simply averaging the treatment effects across households.

Third, while most models on family policies consider agents that live for two periods and abstract away from the pension system, this paper explicitly models a multi-period life cycle with a PAYG system of Social Security. Beyond making the model more realistic, this ingredient allows me to quantify the *demographic structure effect* of family policies: following an increase in the population growth rate, the burden of pension payments is relieved, but public expenditures for children rise. Despite being one of the most important goals that governments have in mind when they implement family policies, the quantitative feasibility of this mechanism is little studied. This paper fills the gap.

Last, unlike most models with endogenous fertility where each child costs a fixed amount of time (Jones et al., 2008), I consider *endogenous childcare choices* where parents can choose to either take care of children by themselves or utilize market childcare services. Besides allowing the model to generate childcare utilization patterns in the data that are otherwise hard to explain, this ingredient allows the model to inform one of the most important discussions about family policies in practice: should the government use cash transfers (e.g., baby bonuses or child allowances) or in-kind benefits (e.g., subsidized childcare vouchers)?

Through the lens of the model, I show that fertility elasticities across households are the key moments disciplining the strength of the above-mentioned mechanisms. First, aggregate fertility elasticity informs how much family resources are diluted for an average household under counterfactual policies - the quantity-quality trade-off. Second, differential fertility elasticities by parents' education govern the magnitude of the composition effects due to intergenerational transmission of human capital. Last, the plausibility of demographic structure effects depends critically on whether government policies have meaningful impacts on fertility choices.

I discipline fertility elasticities in two ways. First, I calibrate the model to match the U.S. economy in 2010 and identify the elasticity of intergenerational substitution (EGS), a key parameter affecting fertility elasticities.<sup>2</sup> Furthermore, I show that the model's predictions are consistent with the effects of the Alaska Permanent Fund Dividend (APFD), a universal basic income policy that implicitly encourage parents to have more children. Using difference-in-differences methods, I find

<sup>2</sup>As defined in Córdoba et al. (2016) and Córdoba and Ripoll (2019), the elasticity of intergenerational substitution (EGS) quantifies the inter-personal willingness to substitute consumption across generations.

that the APFD increases the completed fertility rate in Alaska by 0.17 children per women and the effect is larger among women with lower education. The policy also lowers the overall college enrollment. In addition to the APFD, I find that quasi-experimental evidence from several other family policies also corroborates the magnitude of the calibrated fertility elasticities in the model.<sup>3</sup> These external validation exercises lends extra credibility for me to use the model to conduct policy counterfactuals.

The policy counterfactual analyses reveal four main findings. First, a baby bonus (cash reward for childbirth) of \$30,000 boosts the average fertility rate in the U.S. from 1.9 children per woman to 2.1 children per woman, the replacement level.<sup>4</sup> The amount of this transfer is similar to the expansions of the maximum payment of the Child Tax Credit (CTC) from 2010 to 2021 in net present value, taking the American Rescue Plan Act of 2021 into account. I find that parents with lower human capital respond more strongly to the baby bonus, raising fertility by a greater proportion. Such a child benefit, however, is not effective in raising child human capital or social mobility. Under the calibrated EGS, parents optimally reduce child education investments by an average of 4% due to the quantity-quality trade-off, and this reduction is larger among low-income parents. The heterogeneous reductions in education investments, coupled with composition effects due to differential fertility responses, lower average human capital by 2% and intergenerational income mobility by 1.6% in the long-run steady-state equilibrium.

Second, despite reductions in average human capital and social mobility, long-run average welfare rises by 1.6% in consumption equivalents under the \$30,000 baby bonus.<sup>5</sup> The key to this result is that as the old-age dependency ratio falls following an increase in fertility, the government is able to reduce tax rates while still balancing the fiscal budget due to a smaller burden of pension payments. This is a novel result showing that despite the negative human capital effects, family policies could improve social welfare through interactions with the pension system.

Third, the welfare consequences for existing agents can be very different from those in transition or in the long-run steady state. During the first few decades of transition, the government will need to finance both direct policy expenses and higher child-related public expenditures as children make up a larger proportion of the population. While the old-age dependency ratio falls gradually, the total dependency ratio overshoots in the first few decades before converging to its long-run level. If the government, for example, chooses to balance the budget from period to period using changes in the consumption tax, most households in the current economy will bear higher tax burdens. These

<sup>3</sup>Additional validation exercises include comparisons with the Australian baby bonus, the Spanish child benefits, and the Maternal Capital in Russia. See Appendix D for details.

<sup>4</sup>I use the replacement fertility as a benchmark policy goal since it is “widely considered among policy makers and the public as the desirable level of long term fertility” (Striessnig and Lutz, 2013). Section 6 discusses whether this goal is optimal in itself from a welfare point of view.

<sup>5</sup>Long-run welfare is defined as the average utility of a new-born under the veil of ignorance. See Section 6 for further discussion.

additional expenditures in transition are quantitatively significant. Therefore, policy discussions should not only focus on the long-run gains in alleviating pension liabilities, but should also devote more attention to the financing challenges and distributional consequences along the transition path.

Last, I compare baby bonuses with subsidized childcare and expanded public education funding. I find that these in-kind policies are less cost-effective in raising fertility than the cash rewards but offer other advantages. In particular, subsidized childcare encourages parents to work in the labor market because it substitutes home production of childcare with market childcare services. The resulting increase in working hours, especially among parents with low human capital, reduces wage inequality. Among all policy instruments studied in this paper, public education most effectively improves children's outcomes and boosts social mobility. However, it also has the smallest effect on fertility.

## Related Literature

This paper is most related to the macroeconomic literature with families and endogenous fertility choices. Notable examples include [Barro and Becker \(1989\)](#), [Greenwood et al. \(2003\)](#), [de La Croix and Doepke \(2003\)](#), [Doepke \(2004\)](#), [Erosa et al. \(2010\)](#), [Manuelli and Seshadri \(2009\)](#), [Darulich and Kozlowski \(2020\)](#), [Córdoba et al. \(2019\)](#), [Jones \(2020\)](#), [Kurnaz and Soytas \(2019\)](#), [Cavalcanti et al. \(2021\)](#), and [Ortigueira and Siassi \(2022\)](#) among many others. The conventional wisdom in the literature is that pro-natal policies lower human capital due to the quantity-quality trade-off and reduce average welfare. This paper makes four contributions to the literature. First, I argue that in a setting with multi-period life cycle, lower human capital is not always associated with reduced average welfare because of the demographic structure effects, i.e., the interaction between endogenous fertility and the PAYG pension system. Second, I find that pro-natal policies do not necessarily come at the cost of lower human capital. There exist policies, such as education subsidies, that raise both fertility and human capital at the same time. Third, I show that fertility elasticities are the key moments disciplining fertility-related mechanisms in this class of models. Thus, I establish a connection between the macro literature and empirical studies estimating fertility elasticities using policy variations. Last, I make a model contribution by developing a comprehensive framework tailored to analyzing family policies. In this regard, models in [Manuelli and Seshadri \(2009\)](#), [Darulich and Kozlowski \(2020\)](#), [Liao \(2013\)](#), and [Kim et al. \(2021\)](#) are the most-related ones albeit asking different research questions. The present model differs by adding heterogeneities to [Manuelli and Seshadri \(2009\)](#), adding human capital formation to [Darulich and Kozlowski \(2020\)](#), and adding multi-period life cycle with a PAYG pension system to [Liao \(2013\)](#) and [Kim et al. \(2021\)](#).<sup>6</sup> Furthermore, this model adds endogenous usage of market care to enable the comparison between cash

<sup>6</sup>To explain the positive fertility-income relationship in South Korea, [Kim et al. \(2021\)](#) considers status competition, an ingredient that my model does not have.

transfers and childcare subsidies.

The paper also contributes to a growing literature evaluating the impacts of transfers to parents on children’s lifetime outcomes, social mobility, and inequality (Dahl and Lochner (2012), Daruich (2018), Abbott et al. (2019), Mullins (2019), and García et al. (2020)). The conventional wisdom in the literature is that transfers to families have positive and significant impacts on existing children, including improving health and education attainment and reducing criminal behavior (Schanzenbach et al., 2021). My paper differs by incorporating endogenous fertility responses while using estimates from this literature to quantify the human capital formation part of the model. Adding the fertility margin allows me to study the policy impacts on all children, including those that are induced to be born by the policy itself. I show that under empirically plausible fertility elasticities, introducing the “extensive margin” of fertility choice reverses the predicted policy effects on the average outcome of children and intergenerational mobility in many cases. Most importantly, besides the quantity-quality trade-off *within* households, the composition effects induced by heterogeneous fertility responses *across* households create a wedge between the observed short-run treatment effects and the equilibrium long-run outcome. This wedge should be taken into account in policy evaluations and counterfactuals. In particular, government transfers that are tied to the number of children, such as the CTC or the Universal Basic Income, might have unintended consequences.

Finally, this paper is related to the empirical studies on the fertility effects of family policies (e.g., Milligan, 2005; Haan and Wrohlich (2011), Drago et al., 2011; González, 2013; Laroque and Salanié, 2014; Gaitz and Schurer, 2017). These papers leverage variations from historical policies to study how government transfers affect fertility choices among an existing group of (potential) parents. My paper contributes to this literature by providing a structural-based method to project the fertility effects of family policies across households and over time.

The rest of the paper is organized as follows. In Section 2, I present the quantitative model. Section 3 describes the calibration of the model in detail. I conduct validation exercises in Section 4. Section 5 presents the main policy counterfactual results of the paper. Section 6 discusses optimal policy design and Section 7 concludes.

## 2 Model

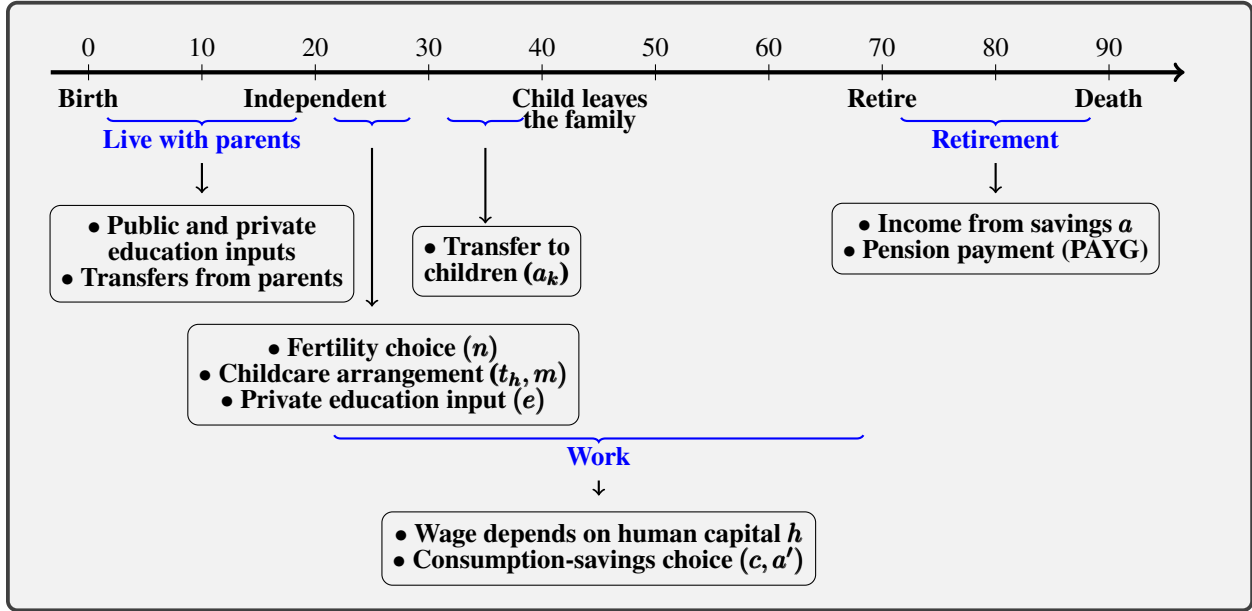

I study a general-equilibrium overlapping generations (GE-OLG) economy. Households make choices over consumption and saving, child quality and quantity, and childcare. Representative firms hire labor and borrow capital from households. The government finances public education, pension payments, and other (exogenous) spending using income and consumption taxes. Appendix A presents a battery of robustness checks on modeling assumptions, including alternative preferences (e.g., dynastic altruism), endogenous timing of childbirth, end-of-life bequests, and different

ways of financing government expenditures.

## 2.1 Household

Consider overlapping generations of households that live up to 90 years. I split the life cycle into 9 periods indexed by  $j \in \{0, 1, 2, \dots, 8\}$ , each representing 10 years. Period  $j$  therefore reflects age  $j \times 10$  through  $(j + 1) \times 10$ .

Figure 1: Model's Life Cycle

The life cycle of each agent in the model is presented in Figure 1. Children live with their parents from age 0 to 20, during which time they make no choices and receive human capital investments from both public and private sources. Children also receive inter vivos transfers from parents when they become independent and form families in their 20s. Households choose fertility, childcare arrangements, and private child human capital investments from age 20 to 30. Between ages 30 and 40, parents determine the amount of inter vivos transfers that their children would receive at the beginning of the next period.

People work from age 20 to 70, and their earnings depend on the amount of efficiency units, i.e., human capital, supplied to the market. Human capital for working adults evolves over time following an age-dependent learning-by-doing process:

$$h_{j+1} = L_j(h_j, t_w, z_{j+1}), \quad (1)$$

where  $z_{j+1}$  is an idiosyncratic, uninsurable shock to human capital that occurs at the beginning of

period  $j + 1$ ;  $h_j$  is the amount of human capital at period  $j$ ; and  $t_w$  is the time worked in period  $j$ . Agents have unit time endowment and supply labor inelastically, with the exception of period 2 where they trade off providing childcare at home against supplying labor in the market.

Agents retire at the end of period 6 (age 60 to 70). Retired adults receive income from savings and pension payments for the remainder of their lives. Households make consumption-savings choices in each period and face an age-specific survival rate  $\delta_j$ .

At the beginning of period 2 (age 20 to 30), the state variables for young adults are the human capital level  $h$  and assets  $a$ . Both  $h$  and  $a$  are endogenously determined in equilibrium by the young adults' parents during previous periods. Agents choose consumption  $c$ , savings  $a'$ , fertility  $n$ , total time spent providing at-home childcare  $t_h$ , amount of market childcare purchased for each child  $m$ , and private education investment for each child  $e$ .<sup>7</sup> Parents' value  $V_2(\cdot)$  is composed of flow utility from consumption  $u(c/\Lambda(n))$  and the discounted continuation value  $\beta V_3(\cdot)$ . Consumption expenditure  $c$  is divided by equivalence scale  $\Lambda(n)$ .<sup>8</sup> Their maximization problem is given by

$$V_2(h, a) = \max_{c, a', n, t_h, m, e \geq 0} u(c/\Lambda(n)) + \beta \mathbb{E} V_3(h', a', n, \mathbb{E} h_k)$$

subject to

$$n \cdot \chi = \left( t_h^{v/\iota} + (n \cdot (m + \mathcal{S}))^v \right)^{1/v}, \quad [\text{time cost}]$$

$$y = wh \cdot (1 - t_h), \quad [\text{labor income}]$$

$$(1 + \tau_c)(c + p_m \cdot n \cdot m + e \cdot n) + a' = (1 + r)a + y - \mathcal{T}(y, a, n) + \mathcal{B} \cdot n, \quad [\text{BC}]$$

$$h' = L_2(h, 1 - t_h, z'), \text{ and} \quad [\text{learning OTJ}]$$

$$h_k = G(h, \mathcal{E}, e, \epsilon). \quad [\text{skill formation}]$$

To raise  $n$  children, parents need to produce  $n \cdot \chi$  amount of childcare (in time units). Parents could satisfy this need either by spending their own time at home ( $t_h$ ) or by purchasing market childcare services  $m$ . The government can provide in-kind childcare  $\mathcal{S} \in [0, \chi]$  free of charge to parents. These two forms of childcare are combined in a constant-elasticity-of-substitution (CES) production function where  $v$  governs the elasticity of substitution. Household production of child-

<sup>7</sup>Following Barro and Becker (1989), de La Croix and Doepke (2003), and most subsequent work, the fertility choice  $n$  is continuous in the model. An alternative approach is to use discrete fertility and add states or idiosyncratic shocks (e.g., Daruich and Kozlowski, 2020). Since the model is calibrated to match aggregate moments on income-fertility relationship, the second approach yields similar results once the additional state space are integrated over.

<sup>8</sup>As defined by Browning et al. (2013), "An equivalence scale is traditionally defined as the expenditures of the household divided by the expenditures of a single person that enjoys the same 'standard of living' as the household. Just as a true cost of living price index measures the ratio of costs of attaining the same utility level under different price regimes, equivalence scales are supposed to measure the ratio of costs of attaining the same utility level under different household compositions."

care enjoys an economy of scale with parameter  $\iota \in (0, 1)$ . This captures the fact that taking care of two children at home simultaneously costs less than two times the hours needed to take care of a single child (Folbre, 2008).

The opportunity cost of home production of childcare  $t_h$  is hours spent in the labor market. The household's labor income  $y$  is the product of the market wage  $w$ , human capital  $h$ , and time worked  $(1 - t_h)$ . Total resources available to the parents consist of risk-free assets  $a$  multiplied by the gross interest rate  $(1 + r)$ , labor income  $y$ , net taxes paid  $\mathcal{T}(y, a, n)$ , and the total amount of baby bonuses received  $\mathcal{B} \cdot n$  where  $\mathcal{B}$  is chosen by the government. The household divides resources into savings  $a'$  and different expenditures, including consumption  $c$ , total spending on market childcare  $p_m \cdot n \cdot m$ , and private education expenditures  $e \cdot n$ . I use  $p_m$  to denote the price of market childcare relative to consumption goods.<sup>9</sup> All expenditures are subject to a proportional consumption tax  $\tau_c$ .

The child human capital production function  $G(h, \mathcal{E}, e, \epsilon)$  combines parents' human capital  $h$ , public education  $\mathcal{E}$ , private investment  $e$ , and idiosyncratic ability shocks  $\epsilon$  which are unknown to the parents. To keep the model tractable, I assume that the function  $G(\cdot)$  captures the overall human capital production function that spans age 0 to 20 without explicitly modeling several stages of production. Moreover, to the extent that the bulk of childcare needs  $n \cdot \chi$  are non-educational (i.e., preparing food or changing diapers), it is assumed that childcare arrangements do not affect child human capital directly in the model (see Mullins (2019)). Parents can invest in their children's human capital through monetary investments  $e$ . As the government chooses public education expenditures  $\mathcal{E}$ , the model could replicate the public provision of high-quality childcare or pre-K by adopting high  $S$  and  $\mathcal{E}$  at the same time.

In the economy, households face an inter-temporal borrowing constraint  $a' \geq 0$  that is standard in the class of Aiyagari-Bewley-Huggett models. Moreover, parents cannot invest negative amounts of resources in children's education, i.e.,  $e \geq 0$ . As a result, public investment  $\mathcal{E}$  serves as a lower bound of the total education investment received by each child.

Parents' maximization problem from age 30 to 40 is given by

$$V_3(h, a, n, \mathbb{E}h_k) = \max_{c, a', a_k \geq 0} u(c/\Lambda(n)) + \beta \mathbb{E}V_4(h', a') + v(n, \mathbb{E}h_k, a_k)$$

subject to

$$y = wh,$$

$$(1 + \tau_c)c + a' + n \cdot a_k = (1 + r)a + y - \mathcal{T}(y, a, n), \text{ and} \quad (2)$$

<sup>9</sup>In the model, the supply of childcare services is perfectly elastic at baseline price  $p_m$ . Since each period represents ten years, adjustments of capital and labor in and out of the childcare industry equate childcare prices to long-run marginal costs so long as the industry is perfectly competitive. In the short run, relative prices of childcare may change in response to family policies if the capacity of childcare is limited and mitigate the policy effects.

$$h' = L_3(h, 1, z'),$$

where parents choose consumption, savings, and the amount of transfers to be received by each child at the beginning of the next period ( $a_k$ ).<sup>10</sup> Parents face intergenerational borrowing constraints so that they are not allowed to make negative transfers to children, i.e.,  $a_k \geq 0$ . I use  $v(n, \mathbb{E}h_k, a_k)$  to denote parents' preferences over child quantity, child human capital, and inter vivos transfers. I discuss the parametric form of  $v(\cdot)$  in detail in Section 3.1.

For  $j \in \{4, 5, 6\}$ , households solve a simple consumption-savings problem with idiosyncratic shocks to human capital. The maximization problem is given by

$$V_j(h, a) = \max_{c, a' \geq 0} u(c/\Lambda(0)) + \beta \delta_j \mathbb{E}V_{j+1}(h', a') \quad j \in \{4, 5, 6\}$$

subject to

$$(1 + \tau_c)c + a' = (1 + r)a + y - \mathcal{T}(y, a, 0) \text{ and}$$

$$h' = L_j(h, 1, z).$$

Finally, retired agents solve

$$V_j(h, a) = \max_{c, a' \geq 0} u(c/\Lambda(0)) + \beta \delta_j V_{j+1}(h, a') \quad j \in \{7, 8\}$$

$$(1 + \tau_c)c + a' = (1 + r)a + \pi \cdot wh - \mathcal{T}(0, a, 0) \text{ and}$$

$$V_9(\cdot) \equiv 0,$$

where household income is composed of risk-free assets and pension payments  $\pi \cdot wh$ , and where  $\pi$  denotes the pension replacement rate.

## 2.2 Firms

There is a representative firm in the economy that hires labor and borrows capital from households to produce final goods with Cobb-Douglas technology

$$Y = AK^\alpha H^{1-\alpha}. \quad (3)$$

In Equation (3),  $K$  is aggregate capital used in production and  $H$  is total efficiency units employed. Without loss of generality, we normalize total factor productivity  $A$  to one.<sup>11</sup>

<sup>10</sup>I discuss the robustness of the main results when I add end-of-life bequests to the model in Appendix A.4.

<sup>11</sup>I abstract away from population externalities that could affect aggregate production such as pollution (Bohn and Stuart, 2015) and idea creation (Jones, 2020). This choice is made since (1) the literature on the measurement of

Physical capital depreciates at rate  $\delta_K$  after use. With competitive factor markets, the equilibrium wage and risk-free interest rate are given by

$$r = \alpha \left( \frac{K}{H} \right)^{\alpha-1} - \delta_K \quad \text{and} \quad w = (1 - \alpha) \left( \frac{K}{H} \right)^{\alpha}.$$

## 2.3 Government

The government collects revenues from taxing labor income, capital income, and household expenditures (including spending on market childcare and children's education). Government expenditures include public education, family policies, pension payments, and other policy-invariant expenditures, denoted  $\Omega$ , that depends on the mass of adults. The government balances the budget from period to period. In the benchmark economy, I set both  $\mathcal{B}$  and  $\mathcal{S}$  to zero.

I use  $\{\mu_j\}_{j=0}^8$  to denote the distribution of households across the state space and  $\{\omega_j\}_{j=0}^8$  to denote the fraction of each age group in the population, with the total mass normalized to one at each date. The government budget is given by

$$\begin{aligned} & \underbrace{\left( \sum_{j=2}^6 \omega_j \int \mathcal{T}(y_j^*, a_j^*, n_j^*) d\mu_j \right)}_{\text{labor and capital income taxes}} + \underbrace{\tau_c \left( \sum_{j=2}^8 \omega_j \int c_j^* d\mu_j + \omega_2 \int n^* \cdot (p_m \cdot m^* + e^*) d\mu_2 \right)}_{\text{consumption taxes}} = \underbrace{(\omega_0 + \omega_1) \cdot \mathcal{E}}_{\text{mass of children} \cdot \text{public education expenditures}} \\ & + \underbrace{\pi \cdot \left( \sum_{j=7}^8 \omega_j \int wh d\mu_j \right)}_{\text{pension payments}} + \underbrace{\omega_2 \left( \underbrace{\int n^* \cdot \mathcal{B} d\mu_2}_{\text{baby bonus}} + \underbrace{\int (1 + \tau_c) \cdot n^* \cdot p_m \cdot \mathcal{S} d\mu_2}_{\text{subsidized childcare}} \right)}_{\text{family policy expenditures}} + \underbrace{\sum_{j=2}^8 \omega_j \cdot \Omega}_{\text{other spending}}. \end{aligned} \quad (4)$$

## 2.4 Equilibrium

I use  $t$  to denote time. The equilibrium of the economy is defined as a tuple composed of:

- decision rules  $\{c_t^*, a_t'^*, n_t^*, m_t^*, t_{h,t}^*, e_t^*, a_{k,t}^*\}_{t=0}^{\infty}$ ,
- prices<sup>12</sup>  $\{w_t^*, r_t^*\}_{t=0}^{\infty}$ ,
- government policies  $\{\mathcal{T}_t(\cdot), \tau_{c,t}, \mathcal{B}_t, \mathcal{S}_t, \mathcal{E}_t\}_{t=0}^{\infty}$ , and
- distribution of agents  $\{\{\mu_{j,t}\}_{j=0}^8, \{\omega_{j,t}\}_{j=0}^8\}_{t=0}^{\infty}$ ,

population externalities is still developing, and (2) the results will change in expected ways once positive/negative externalities are incorporated.

<sup>12</sup>Recall that the relative price of childcare  $p_m$  is exogenous in the model.

such that households maximize utility subject to idiosyncratic shocks, prices clear labor and capital markets, the government balances the budget in each period, and the distribution of agents evolves following the dynamics shaped by household decision rules, exogenous human capital shocks  $z$ , and the ability shock for children  $\epsilon$ .

The evolution of the human capital distribution from parents to children is given by

$$\mu'_2(h) = \frac{1}{N} \iint n^*(x) \mathbb{1}_{h_k^*(x, \epsilon) < h} d\mathcal{Q}(\epsilon) d\mu_2(x), \quad (5)$$

where  $\mathcal{Q}$  denotes the distribution of the child ability shock  $\epsilon$ . Variable  $h_k^*(x, \epsilon)$  is the human capital of a child whose ability shock is  $\epsilon$  and parents' human capital is  $x$ .  $N$  is the aggregate fertility rate in the economy defined as:

$$N = \int n^*(x) d\mu_2(x). \quad (6)$$

In a stationary equilibrium of the economy, decision rules, prices, and distributions are unchanged over time. The size of the population, however, could vary over time as the aggregate fertility rate is not necessarily at the replacement level. Under mild conditions that are satisfied by the model, a stationary distribution exists and is unique (see [Mode, 1971](#); [Chu, 1990](#)).

## 2.5 Welfare

To facilitate comparisons between different government policies, I define social welfare in the long run ( $\mathcal{W}$ ) as the *average value* of households at the beginning of their life cycle:

$$\mathcal{W} = \int V_2 d\mu_2, \quad (7)$$

where both  $V_2$  and  $\mu_2$  are endogenous equilibrium objects. The welfare metric  $\mathcal{W}$  measures the expected utility of a newborn child under the veil of ignorance by summing up the discounted utility flow from later life periods. When making welfare comparisons, I convert the changes in  $\mathcal{W}$  into percentage changes in consumption equivalents. Since the welfare metric  $\mathcal{W}$  does not reflect the policy effects for households who are *already alive* when the policy is enacted, or for those who will be born in the *transition phase*, I assess how these people are affected by family policies in Section 5.3. Section 6.1 discusses alternative welfare measures.

In the model, government policies have the potential to improve the well-being of agents for two reasons. First, childbearing and child-rearing carry fiscal externalities as parents do not internalize the effects of having an additional child or investing in child human capital on the future tax base and government revenues. Atomic parents take the age structure  $\{\omega_j\}_{j=0}^8$ , distribution  $\{\mu_j\}_{j=0}^8$ , and tax rates as given, but these objects will change when a mass of parents adjust their decisions on fertility

and education investments. Following this line of logic, [Schoonbroodt and Tertilt \(2014\)](#) argue that due to parents' lack of property rights over children's future output, the equilibrium level of fertility is too low relative to the planner's solution. Different from [Schoonbroodt and Tertilt \(2014\)](#), in a model with heterogeneous agents and public transfers (i.e., taxes, education, and pension), the equilibrium fertility could be either too high or too low depending on parental characteristics.<sup>13</sup>

Second, parents face both inter-temporal and intergenerational borrowing constraints due to imperfections in capital markets. Parents cannot borrow against their children's future income or their own future income to finance current expenditures. Government policies can overcome these inefficiencies by providing in-cash or in-kind transfers ([Daruich, 2018](#); [Abbott et al., 2019](#)).

## 2.6 Discussion of Mechanisms

In this section, I discuss the mechanisms through which family policies affect the economy. In particular, I highlight how the features of this model (namely, fertility and child quality choice, endogenous demographic structure, and childcare arrangements) make the model's predictions on the overall impacts of family policies distinct from those in standard models.

### 2.6.1 Quantity-Quality Trade-Off

Consider the effect of an increase in the baby bonus  $\mathcal{B}$  on private education investment into child human capital formation  $e$ , which determines children's expected human capital  $\mathbb{E}h_k$ . The same argument applies to inter vivos transfers  $a_k$ . The first-order condition of  $e$  is given by

$$\underbrace{MU_c \cdot n}_{\text{marginal costs of } e} = \underbrace{\frac{\partial v(n, \mathbb{E}h_k, a_k)}{\partial \mathbb{E}h_k} \times \frac{\partial \mathbb{E}h_k}{\partial e}}_{\text{marginal benefits of } e}. \quad \text{FOC } [e]$$

When fertility is exogenous, i.e.,  $n$  is fixed, the increase in  $\mathcal{B}$  is an *income transfer*, which implies that  $e$  rises unambiguously due to income effects. As the marginal utility of consumption  $MU_c$  decreases,  $e$  needs to increase to keep the first-order condition satisfied.

When fertility is endogenous, however, the increase in  $\mathcal{B}$  is a *price change*. The direction in which  $e$  changes is ambiguous. As fertility  $n$  rises due to more generous child benefits, it affects the first-order condition in three ways. First, it interacts with  $e$  in parents' preferences  $v(\cdot)$ . If quality and quantity are complements, parents demand higher  $e$  *ceteris paribus*, and vice versa.<sup>14</sup> Second,

<sup>13</sup>The policy implications of this observation, however, are less straightforward than one might think. Due to intergenerational persistence of human capital, a tempting conclusion is that the policymaker should restrict fertility among the poor ([Chu and Koo, 1990](#)). Setting aside the rampant ethical concerns over such a policy, I show that this argument is not valid in Sections 5.1 and 6.3.

<sup>14</sup>Whether child quantity and quality are complements or substitutes remains an open question in the literature.

rising quantity could potentially offset the income effect since higher  $n$  raises the marginal utility of consumption via the change in the equivalence scale  $\Lambda(n)$ . Last, the marginal cost of  $e$  rises because it is proportional to fertility  $n$  due to their interaction in parents' budget constraint (see Equation (2)).<sup>15</sup> Considering endogenous fertility allows for the possibility that  $e$  - hence children's human capital  $h_k$  - could fall when family policies become more generous. In Section 5.1, I show that both indeed fall in the calibrated model.

## 2.6.2 Composition Effects

Because parents differ by human capital  $h$  and asset holdings  $a$ , they respond differently to the same baby bonus  $\mathcal{B}$  or subsidized childcare  $\mathcal{S}$ .<sup>16</sup> With an endogenous quantity-quality trade-off, children from families with stronger fertility responses account for a larger fraction of the future population. Combined with the intergenerational transmission of traits, differential fertility responses results in *composition effects* whereby aggregate variables gravitate towards those of the households with the largest fertility responses.

For example, consider the average human capital of children in the economy

$$\underbrace{\bar{h}_k}_{\text{average } h_k} = \iint \underbrace{\frac{n^*(h, a)}{N}}_{\text{fertility weight}} \cdot \underbrace{h_k^*(h, a, \cdot)}_{\text{individual child's } h_k} d \underbrace{\mu_2}_{\text{parents' dist.}} d\epsilon,$$

where  $N$  is the aggregate fertility rate defined in Equation (6). Family policies change fertility weights  $n^*(h, a)/N$  across households. As a result, even when  $h_k^*(h, a, \cdot)$  stays unchanged,  $\bar{h}_k$  converges towards families with rising fertility weights.

From a theoretical perspective, composition effects generate an interesting scenario where aggregate human capital decreases even if policy effects on individual children's human capital are positive. Empirically speaking, composition effects are shown to be important for the evolution of aggregate variables such as economic growth (de La Croix and Doepke, 2003) and public opinion on family values (Vogl and Freese, 2020).

Standard Barro-Becker models usually assume they are complements (e.g., Córdoba et al., 2016; Daruich and Kozlowski, 2020). On the other hand, there are also models using separable preferences (e.g., de La Croix and Doepke, 2003; Bar et al., 2018), or quality and quantity being substitutes (Jones and Schoonbroodt, 2010).

<sup>15</sup>Becker and Lewis (1973) named this last effect the quantity-quality trade-off. In this paper, I abuse this term slightly to denote the overall effect of an increase in fertility on child quality. Using twin births as instruments, some recent papers (e.g., Black et al., 2005 and Angrist et al., 2010) find little evidence of such a trade-off. A recent study by Mogstad and Wiswall (2016), however, overturns that conclusion by relaxing the linear specification constraint. They find evidence of a trade-off between quality and quantity for larger families and complementarities in small families.

<sup>16</sup>See Drago et al., 2011 and Table 3 for empirical evidence.

### 2.6.3 Demographic Structure Effects

With endogenous fertility, family policies change the population growth rate, and, as a result, the demographic structure  $\{\omega_j\}_{j=0}^8$ . This has profound implications for the government budget constraint (4) because demographic structure determines how each source of revenue or expenditure is weighted.

Most macroeconomic structural models with endogenous fertility assume two-period-lived agents or do not put much emphasis on the existing pension system. From the government budget perspective, an increase in the population growth rate leads to an unambiguous increase in the fiscal burden in this class of models since there are fewer tax-paying adults to finance public education expenditures for children. Therefore, tax rates need to rise to balance the budget. Most developed countries that actually adopt family policies, however, have a different story in mind where tax rates should be *lower* instead of higher in the long run. The key missing piece in the previous analyses is the presence of retired households receiving pension payments.

In an economy with multi-period life cycle, the effects of higher population growth rate on budget-balancing tax rates is ambiguous as it depends on the profile of net government transfers that agents receive by age. Holding human capital constant, higher fertility reduces tax rates in the long run if pension payments are larger relative to the expenditures on children. This mechanism leads to potential welfare gains with a simple intuition - under a PAYG pension system, all households are better off if the size of incoming cohorts are growing rather than shrinking.

To analyze this mechanism, I denote the effects of family policies through changes in the mass of each age group as *demographic structure effects*.

### 2.6.4 Childcare Choices

Consider a comparison between two family policies, a baby bonus  $\mathcal{B}$  and subsidized childcare  $\mathcal{S}$ . In standard macroeconomic models with endogenous fertility, each child costs a fixed amount of time for parents.<sup>17</sup> Since subsidized childcare reduces time costs, total income in this class of models is given by

$$y = wh \underbrace{(1 - (\chi - \mathcal{S}) \cdot n)}_{\text{hours worked}} + n \cdot \mathcal{B}.$$

For parents with human capital  $h$ , a baby bonus  $\mathcal{B}$  can be replicated by subsidized childcare with  $\mathcal{S} = \frac{\mathcal{B}}{wh}$  in these models. Therefore, parents should be indifferent between in-cash and in-kind child

<sup>17</sup>Modeling child costs as time costs rather than goods costs is crucial for explaining the negative income-fertility relationship (Jones et al., 2008). See the discussion in Doepke and Tertilt (2016). A notable exception that considers the use of market childcare is Bar et al. (2018). Those authors show that the adoption of market childcare services and rising income inequality explain the recent rise in fertility among high-income married women in the U.S.

benefits of the same face value. They are also expected to react to each policy in the same way in terms of labor supply and child-related decisions.

These predictions from traditional models are not supported by empirical evidence which indicate that parents react differently to in-cash versus in-kind benefits. Upon receiving a baby bonus, parents do not increase their labor supply but rather choose to stay at home and use less market childcare ([González, 2013](#)). In contrast, upon receiving subsidized childcare, parents increase their labor supply drastically and substitute home care for (subsidized) market care ([Milligan, 2005](#)). Last, use of market childcare is increasing in maternal education.<sup>18</sup> Models without childcare arrangements are unable to account for this pattern.

In this model, considering parents' childcare arrangements provides an explanation for patterns observed in the data and offers a natural way to compare family policies of different kinds. With market childcare, a substitute for home care, available at a uniform price, richer parents use more market childcare services than poorer ones. A government-offered childcare subsidy  $S$  will therefore be equivalent to a baby bonus  $B$  of the same face value for parents with high human capital who are already spending more than  $S$  on market childcare – subsidized childcare simply reduces their out-of-pocket expenditures. On the other hand, parents with low human capital who receive a childcare subsidy  $S$  would rather have an in-cash transfer  $B$  of the same face value since they prefer spending the money on consumption or education. As a result, subsidized childcare  $S$  is “binding” for low-human capital parents in the sense that the in-kind policy pushes them into the labor market if they want to take up the benefits. Their welfare improvements will be smaller than if they were offered a baby bonus  $B$  of the same face value. As they work more, however, these parents accumulate more human capital through learning-by-doing, and the economy sees a reduction in the life-cycle wage inequality across parents.

## 2.7 Summary of Mechanisms

As discussed above, the framework contains a unique mix of modeling ingredients. Therefore, the model explains more observed data patterns (e.g., childcare usage) relative to standard macroeconomic models with endogenous fertility. It also speaks to several important mechanisms through which family policies affect the economy.

The quantitative magnitude of these mechanisms depends crucially on the fertility responses to family policies (the fertility elasticities). For instance, if child quantity is fixed, then family policies will have (1) a simple income effect on children's outcomes, (2) no composition effects, and (3) no demographic structure effects. In [Section 3](#), fertility elasticities across households are disciplined by the calibrated model parameters. In [Section 4](#), I show that the model predictions on fertility

<sup>18</sup>See [Figure 5](#) for evidence. Also see [Bar et al. \(2018\)](#) and [Chaparro et al. \(2020\)](#).

responses are consistent with empirical evidence.

### 3 Calibration

In this section, I discuss the parameterization, calibration procedures, and the model fit. Following the literature, I choose some parameters exogenously, most of which either have standard values or have observable counterparts. The other 14 parameters (listed in Table 2) are calibrated inside the model by matching steady-state moments to the United States in 2010.

#### 3.1 Preferences over Quantity and Quality

Parents' preference over child quantity and quality is given by

$$v(n, \mathbb{E}h_k, a_k) = \underbrace{\Psi(n)}_{\text{child discounting}} \cdot \underbrace{(\theta \cdot u(\mathbb{E}h_k) + \nu \cdot u(a_k))}_{\text{utility from quality}}, \quad (8)$$

$$\Psi(n) = 1 - \exp(-\psi n), \text{ and} \quad (9)$$

$$u(x) = \frac{x^{1-\gamma}}{1-\gamma}, \quad \gamma \in (0, 1), \quad x \in \{\mathbb{E}h_k, a_k, c\}. \quad (10)$$

where parents value child quality weighted by the child discounting function  $\Psi(n)$  (c.f., [Barro and Becker, 1989](#); [de La Croix and Doepke, 2003](#); [Kim et al., 2021](#)). The utility function of child quality and consumption is governed by parameter  $\gamma$ , which determines the elasticity of intergenerational substitution (EGS), i.e.,  $1/\gamma$ , defined in [Córdoba et al., 2016](#) and [Córdoba and Ripoll \(2019\)](#).<sup>19</sup> I use  $\theta \cdot u(\mathbb{E}(h_k)) + \nu \cdot u(a_k)$  as a first-order approximation to general preferences over child quality and transfers. In Appendix A.2, I argue that results in this paper are robust to other common specifications used in the literature, including separable preferences ([de La Croix and Doepke, 2003](#)), quality and quantity being substitutes ([Jones and Schoonbroodt, 2010](#)), and dynastic altruism (?).

I calibrate parameters  $\theta = 2.85$  and  $\nu = 0.29$  to match the average human capital investment as a share of income and average inter vivos transfers of \$48,381 in 2000 dollars ([Daruich, 2018](#)).<sup>20</sup> I

<sup>19</sup>Since the EGS is designed to match interactions across generations, its magnitude and interpretations are different from that of the elasticity of intertemporal substitution (EIS) used to capture risk-aversion in business cycle models. More specifically, when utilities from consumption and child quality are separable, it is common to assume that EIS and EGS are the same to ensure the existence of long-run steady states (see [Barro and Becker, 1989](#); [Soares, 2005](#)). For recent work modeling EGS and EIS jointly with non-separable utilities, see [Córdoba and Ripoll \(2019\)](#).

<sup>20</sup>[Daruich \(2018\)](#) uses the PSID and the CEX to estimate that average expenditures on each child below age 12 include 18 hours of "quality" hours per week and \$1,966 (in 2000 dollars) spent on childcare and education investments. These two expenditures combined amount to 13.4% of median family income. The calibration targets this moment by computing average education investments  $e$  plus expenditures on market childcare services  $m$ . These moments are also

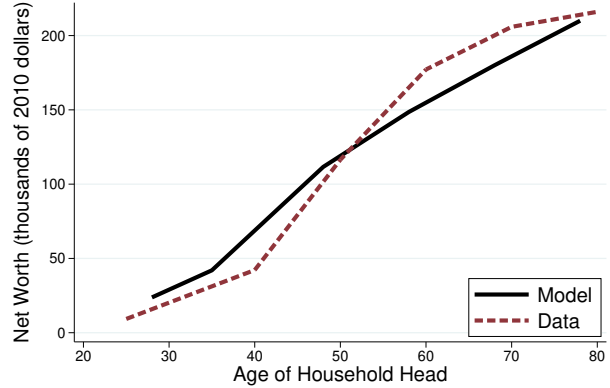

Figure 2: Identification of  $\gamma$ 

Figure 3: Non-Targeted - Net Worth by Age

Notes: Figure 2 plots the relationship between family income and fertility in the model under different  $\gamma$ . Fertility rates by income are calculated using the number of live births ever had for married women between 40 and 55 years old in the CPS Fertility Supplement data from 2008 to 2014.

— Figure 3 plots the median net worth by age in the model and in the data. Median net worth in the model is calculated using net asset position  $a$  integrated over the equilibrium distribution of households by age. In the data, median net worth by age of the household head is collected from the [Federal Reserve System](#) estimated using the Survey of Consumer Finances (SCF).

calibrate  $\psi = 2.3$  to match the average fertility calculated using the CPS Fertility Supplement data from 2008 to 2014.

Conditional on  $\{\theta, \nu, \psi\}$  and other parameters of the model,  $\gamma$  governs the fertility elasticity. Higher  $\gamma$  leads to a faster decay of the marginal utility from  $\{\mathbb{E}h_k, a_k, c\}$ . Hence when the “price” of child falls, parents have larger fertility responses to balance the first-order-condition. The illustrative model in Appendix E.2 highlights this logic. The same argument provides the identification of  $\gamma$  following [Córdoba et al. \(2016\)](#): controlling for other parameters, higher  $\gamma$  implies a faster decay in the marginal utility of consumption as parents get richer, which makes having children more valuable for them as an “extensive margin” of adjustment. As a result, higher  $\gamma$  leads to a flatter income-fertility profile. Figure 2 shows a numerical illustration of the identification. I choose  $\gamma = 0.73$  such that the model best fits the observed relationship between fertility and income.

Even though  $\gamma$  is restricted to be between  $(0, 1)$ , the model generates a surprisingly good fit to the data in terms of life-cycle asset accumulation. Figure 3 shows the median net worth profile from the model and from the Survey of Consumer Finances (SCF). The model generates a non-targeted life-cycle profile of net worth similar to the data both in trend and in levels.

similar to those reported in [Lee and Seshadri \(2019\)](#).

### 3.2 Child's Human Capital Production

I parameterize the child human capital production function as

$$h_k = G(h, \mathcal{E}, e, \epsilon) = \underbrace{Z}_{\text{scalar}} \cdot \underbrace{\epsilon}_{\text{shock}} \cdot \underbrace{h^\rho}_{\text{spillover}} \cdot \left( \underbrace{\mathcal{E}^\xi}_{\text{public education}} + \underbrace{e^\xi}_{\text{private input}} \right)^{\kappa/\xi}, \quad (11)$$

where child ability shock  $\epsilon$  follows  $\log(\epsilon) \sim \mathcal{N}\left(-\frac{\sigma_\epsilon^2}{2}, \sigma_\epsilon^2\right)$

Parameter  $Z$  is a scaling parameter that governs the overall scale of the economy. I choose  $Z = 2.5$  to normalize the median income of families in the model to one, corresponding to the Census-estimated household median income of \$49,445. Parameter  $\sigma_\epsilon$  governs the dispersion of idiosyncratic shocks to children's ability. I pick  $\sigma_\epsilon = 0.58$  to match the dispersion of earnings for households aged 23 to 29 in the CPS-ASEC data (2008-2014). I calibrate  $\rho = 0.30$  to match the rank-rank intergenerational mobility estimated by [Chetty et al. \(2014\)](#). Figure 4 shows that the model generates a good fit both in absolute upward mobility and relative mobility.

I denote  $\xi$  as the elasticity of substitution between public and private education inputs.  $\xi = 0.9$  is calibrated to match the relationship between education spending and household income using data from the Consumer Expenditure Survey (CEX) which includes tuition, test preparation, tutoring, books, and supplies. Public education  $\mathcal{E}$  in the baseline economy is chosen to match the \$12,000 annual expenditure per student reported by the National Center of Education Statistics (NCES). This value translates to 0.16 under the normalization of median income to be 1.

The last parameter to be calibrated is  $\kappa$ . It governs the productivity of education investments. I identify  $\gamma$  using RCT evidence from [García et al. \(2020\)](#). [García et al. \(2020\)](#) evaluate early childhood programs (ABC/CARE) from the 1970s. The yearly cost of the program was \$18,514 per participant (in 2014 dollars) for five years. Treated children were followed into adulthood with education and incomes observed by researchers. [García et al. \(2020\)](#) estimate that children's lifetime labor income increases by 1.3 dollars in net present value for every dollar invested. I take this moment on benefit-cost ratio and compute the model counterpart. More specifically, I apply the same policy in the model by expanding existing public education  $\mathcal{E}$  by \$17,000 (in 2010 dollars) for five years. The policy targets children with parents at the 10<sup>th</sup> percentile of earnings. Moreover, the counterfactual is evaluated at a small scale so that prices and taxes remain unchanged. I calibrate  $\kappa = 0.13$  by matching the benefit-cost ratio in the model to that in [García et al. \(2020\)](#).

### 3.3 Costs of Children and Childcare

The household equivalence scale  $\Lambda(n)$  is taken from the OECD standard:

$$\Lambda(n) = 1.7 + 0.5 \cdot n,$$

where  $n$  is the number of children residing with the family. The base level  $\Lambda(0)$  is 1.7 to correspond to married households.

Recall that the childcare requirement, i.e., time cost of children, is given by

$$n \cdot \chi = \left( t_h^{v/\iota} + (n \cdot (m + \mathcal{S}))^v \right)^{1/v}.$$

I choose  $\chi = 0.18$  following estimates by [Folbre \(2008\)](#) (Table 6.2), calculated using data from the American Time Use Survey (ATUS).<sup>21</sup> I calibrate the economies of scale in providing childcare at home  $\iota = 0.7$  to match the estimates by [Folbre \(2008\)](#) (Table 6.4) where the author finds that for two-parent families, the active parental time per child is 1.5 times higher in one-child families than that of two-child families. The parameter governing the elasticity of substitution between home care and market care  $v$  is calibrated to be 0.38 to match the differential childcare usage by parents' income using data from the National Survey of Early Care and Education (NSECE) (see Figure 5). Last, I set the price of full-time market care for a child aged 0 to 10,  $p_m$ , to be \$6,860 per year in 2010 following the statistic reported by the National Association of Child Care Resource & Referral Agencies ([NACCRRA, 2011](#)).<sup>22</sup> As a non-targeted moment, the model predicts that the average expenditure on childcare as a fraction of total family income is 16% of median income, very similar to the findings in [Herbst \(2018\)](#).

### 3.4 Other Parameters

Human capital of adults evolves with age according to

$$h_{j+1} = L_j(h_j, t_w, z') = \exp(z') [h_j + \zeta_j(h_j \cdot t_w)^\eta] \text{ and} \quad (12)$$

$$\log(z) \sim \mathcal{N}(\mu_z, \sigma_z).$$

<sup>21</sup>[Folbre \(2008\)](#) documents that an average child in a two-parent household spends about 22 hours per week in active non-parental care, and 23 hours per week in active parental care (adjusting for presence of both parents). Therefore, I calculate  $\chi$ , the total active care required by one child as a fraction of parents' total time endowment, as  $\chi = (22 + 23)/((24 - 6.5) \cdot 7 \cdot 2) \approx 0.18$  assuming 6.5 hours of sleep for each parent ([Richter et al. \(2019\)](#)).

<sup>22</sup>The average annual costs of full-time childcare across all U.S. states are \$9,303 (infant), \$7,377 (4-year-old), and \$4,753 (school-age) for child care centers; family child care, on the other hand, costs \$6,926 (infant), \$6,131 (4-year-old), and \$4,405 (school-age) ([NACCRRA, 2011](#) Appendix 1). I take an age-weighted average of these costs to calculate full-time childcare costs for children aged 0 to 10.

Figure 4: Model Matches Mobility

Figure 5: Model Matches Childcare Usage

Notes: Figure 4 plots the relationship between parents' income rank and children's expected income rank in the calibrated model and that estimated by Chetty et al. (2014).

— Figure 5 plots the average weekly non-parental care received by children aged 0-2 conditional on parents' income decile. The data estimate is obtained using the public-use file of the National Survey of Early Care and Education (NSECE) wave 2012 by Flood et al. (2021). They calculate the average weekly non-parental care hours in the data by maternal education categorized into “less than high school”, “high school”, “some college”, and “bachelor's degree and above”. I map the education category into income deciles using median income by education and income distribution estimated from the Current Population Survey (CPS).

I calibrate  $\eta = 1.22$  to match the heterogeneous growth rate of income by initial income decile (see Figure 6).<sup>23</sup> Parameters  $\{\zeta_j\}_{j=2}^5$  and  $\sigma_z = 0.38$  are calibrated to match the life-cycle profile of average household income and its dispersion.<sup>24</sup> I choose  $\mu_z = -0.23$  exogenously so that human capital depreciates at an annual rate of 2%.

Despite matching the Gini coefficient of income by design, the model generates a Gini coefficient of wealth of 0.66, falling short of 0.8 observed in the data. This is a well-known issue for standard Aiyagari-Bewley models (Benhabib et al. (2017)). But under the same set of parameters, the Gini coefficient of wealth would have been just 0.5 had the fertility choices been exogenous in this model. This comparison shows that endogenous fertility is a power mechanism shaping the wealth distribution, echoing Scholz and Seshadri (2007) and Daruich and Kozłowski (2020).

Following Heathcote et al. (2017), I parameterize income taxes as

$$\mathcal{T}(y, a, n) = y \cdot (1 - \tau_y^n y^{-\lambda_y^n}) + \tau_a r a, \quad (13)$$

where  $\{\tau_y^n, \lambda_y^n\}$  denote the level and progressivity of taxes depending on the number of children

<sup>23</sup>This model reproduces the well-documented hump-shaped life-cycle earnings profile as well as a Gini coefficient of human capital that is increasing in age (Huggett et al., 2006). These two facts are reconciled by considering a profile of learning ability  $\{\zeta_j\}_{j=2}^5$  that is decreasing in age and the self-production of human capital with  $\eta > 1$ .

<sup>24</sup>I calculate average income by age and the Gini coefficient of income by age using data from married households in the CPS-ASEC data (2008-2014). I have experimented with panel methods à la Huggett et al. (2011) and the results are quantitatively similar.

Figure 6: Income Growth By Initial Decile

Figure 7: Labor Income Taxes

Notes: Figure 6 plots the growth rate of average income from age 25 to 35, depending on the initial income decile at age 25. For married households in the CPS-ASEC data (2008-2014), I calculate the growth rate of average household income by four education categories: “less than high school”, “high school”, “some college”, and “bachelor’s degree and above”. The initial income decile of each education category is calculated using the income distribution at age 25. — Figure 7 plots average tax rates depending on household income and number of dependent children residing with the family calculated TAXSIM.

residing in the household while  $\tau_a$  denotes the linear capital income taxes. I obtain  $\{\tau_y^n, \lambda_y^n\}$  using simulated data from TAXSIM provided by the NBER (see Figure 7) and use linear interpolation to calculate  $\{\tau_y^n, \lambda_y^n\}$  when  $n$  is not an integer. Having an additional child significantly reduces the tax burden faced by households through various programs such as the Earned Income Tax Credit (EITC), Dependent Care Tax Credit (DCTC), and the Child Tax Credit (CTC). The tax system is progressive, with lower-income households receiving subsidies. As household income grows, labor income taxes converge to 40%. Following [McDaniel \(2007\)](#) and [Darulich and Fernández \(2020\)](#), I choose capital income tax  $\tau_a = 0.27$  and consumption taxes  $\tau_c = 0.07$ . The pension replacement rate  $\pi$  is set to 40%.

In the production function of the representative firm, I choose the capital share  $\alpha$  to be 0.33 following the standard in the literature and set the capital depreciation rate  $\delta_k$  at 4% per year. Last, I choose the annual discount rate  $\beta = 0.98$  and calculate the age-specific mortality rate  $\{\delta_j\}_{j=0}^8$  using the [actuarial life table](#) from the Social Security Administration.

Table 1 summarizes the model parametrization, and Table 2 contains the list of identifying moments and the model fit. As all the moments affect all the parameters, it is difficult to pinpoint which moment is identifying a certain parameter. Nevertheless, Table 4 in Appendix A displays the sensitivity of model parameters to change in moments. Table 5 in Appendix A displays the elasticity of moments to model parameters to illustrate the identification argument.

Table 1: Calibrated Parameters

Interpretation	Value	Source	Interpretation	Value	Source
Preferences			Child human capital production		
$\beta$	discount rate (annual)	0.98	standard		
$\gamma$	elasticity of substitution	0.73	CPS		
$\psi$	fertility preference	2.30	CPS		
$\theta$	quality preference	2.85	PSID		
$\nu$	transfer preference	0.29	PSID		
Childcare arrangement			Adults' human capital evolution		
$\chi$	childcare cost	0.18	ATUS		
$\iota$	economies of scale at home	0.7	ATUS		
$\nu$	substitutability of care	0.38	SIPP		
$p_m$	price of full-time care	\$6,860	NACCRA (2011)		
Taxes and pension			Firm production function		
$\tau_y^n, \lambda_y^n$	tax levels and progressivity	misc.			
$\tau_c$	consumption tax	0.07	McDaniel (2007)		
$\tau_a$	capital income tax	0.27	McDaniel (2007)		
$\pi$	pension replacement rate	0.40	OECD Database		

Notes: This table displays the list of parameters used in the model. Parameters in red are calibrated within the model while those in black are chosen exogenously.

Table 2: Identifying Moments and Model Fit

Parameter	Interpretation	Moment	Data	Model
$\gamma$	elasticity of substitution	fertility-income profile (Figure 2)	misc.	misc.
$\psi$	fertility preference	average fertility	1.92	1.92
$\theta$	human capital preference	average investment as % of income	13.4	13.5
$\nu$	transfer preference	average transfer	\$48,381	\$48,400
$\iota$	economies of scale at home	childcare time by # of children	1.5	1.5
$v$	substitutability of care	childcare by parents' income (Figure 5)	misc.	misc.
$Z$	normalizing scalar	median income = 1	N/A	N/A
$\sigma_\epsilon$	ability shock dispersion	Gini of earnings at $j = 2$	0.29	0.29
$\rho$	intergenerational spillover	intergenerational elasticity of earnings	0.34	0.33
$\xi$	substitution of education	investment by parents' education	misc.	misc.
$\kappa$	input productivity	return on per dollar investment (NPV)	\$1.3	\$1.29
$\eta$	learning curvature	income growth by initial decile	0.1	0.09
$\{\zeta\}_{j=2}^5$	learning level	income growth by age	misc.	misc.
$\sigma_z$	shock dispersion	Gini of earnings at $j = 6$	0.39	0.39

Notes: This table displays the list of parameters, identifying moments, and the model fit. See text for more discussion on the source of each moment.

## 4 Validation

In this section, I discuss the main external validation of the fertility and education responses to financial incentives. The purpose of the validation exercises is to lend extra credibility to the quantitative predictions of the model before evaluating policy counterfactual. In Appendix D, I provide further confirmation of the model's predictions using evidence from the Australian baby bonus, the Spanish child benefits, and the Maternal Capital in Russia.

The main validation exercise exploits empirical evidence from the Alaska Permanent Fund Dividends (APFD). The dividend was officially established in 1982 after the discovery of petroleum increased state revenues. Every year, it gives uniform transfers to all residents regardless of income, employment or age. In particular, the program allows a parent, guardian, or other authorized representative to claim a dividend on behalf of a child, while Alaska law imposes no requirements whatsoever on how parents use a child's dividend. As a result, the policy has pro-natal effects even though it is not explicitly advertised as a family policy that encourages fertility.

The APFD is an ideal policy environment to validate fertility elasticities in the model for three reasons. First, compared with other family policies which are usually less than a few thousand dollars in net present value per child (McDonald, 2006; Luci-Greulich and Thévenon (2013)), the net present value that parents could receive and use with an additional child under the APFD is almost \$20,000.<sup>25</sup> With sizable benefits, it is more likely that the APFD would have meaningful

<sup>25</sup>I calculated the average payment to be around \$1,500 per year. Since the amount of the dividend is tied to the performance of the overall stock market, future payment uncertainties might affect people's responses. Given that

and observable impacts on people’s behavior, especially when it comes to the important and irreversible decision of having a child. Second, unlike family policies which are typically means-tested or depend on birth order, the APFD has a simple implementation, with more than 91% of the state population filing for the application historically. In contrast, the Census Bureau estimates that the national participation rate of the Earned Income Tax Credit (EITC) is [lower than 80%](#). Moreover, the APFD mimics a universal basic income for parents plus a fully refundable Child Tax Credit (CTC) for children without income requirements. Given that the APFD is not advertised as a policy that aims to encourage childbirth, its effects on fertility provide a conservative benchmark for family policies that are explicitly pro-natal, and thus may change parents’ behaviors through preferences or information. Last, [Cowan and Douds \(2021\)](#) find that the migration effect, also known as “population magnets effect,” of the APFD was not large empirically, with net migration rates around one-tenth of a percent in the sample period.

To implement the APFD in the model, I transfer \$1,500 (annually) to every household member, including both parents and children. Parents will receive this transfer (for themselves) every period until they die. They are also entitled to receive the children’s share of dividends before their children become independent. I normalize the amount of the transfer by median household income in Alaska relative to the total U.S. I conduct the policy experiment in the partial equilibrium without changing prices and distribution. The model predicts that the completed fertility rate, i.e., the total number of children that parents end up having, increases by 0.16 compared with the scenario without the APFD.<sup>26</sup> The model also predicts heterogeneous fertility responses across households. Since parents are entitled to claim children’s dividends and these dividends are uniform in size, the model predicts that parents with lower human capital will have a larger increase in fertility.

Using the CPS Fertility Supplement data from 1982 to 2018, I collect micro-level data on the completed fertility rate, i.e., the total number of live births ever had, among women aged 40 to 55 (see [Figure B.2](#)). I divide the Alaskan sample into three groups based on the survey years. The “not treated” group contains the data prior to year 1987, as these women had already passed their childbearing years when the APFD was enacted. The “partially treated” group contains the sample from 1987 to 2005 because the APFD affected some, but not all, of their childbearing years. Last, the “fully treated” group contains the observations from 2006 to 2018 since these women fully took the policy into account when making fertility choices. Women in other states are in the control group.

childbirth is an irreversible decision, I argue that a mean-preserving spread of the dividend payment would reduce households’ fertility responses. Therefore, since the model generates fertility elasticities that are consistent with people’s choices under uncertainty, the results on child benefits without uncertainty is likely conservative.

<sup>26</sup>I derive this result by calculating the difference in the aggregate fertility rate between the new stationary equilibrium and the baseline economy without the APFD. Results from the transition path (see [Figure 12a](#)) indicate that the policy effect on fertility is almost unchanged if I use short-run effects in the transition phase instead of long-run ones.

To estimate the policy effects on the completed fertility rate, I use a difference-in-differences strategy by regressing the completed fertility rates on state fixed effects, year fixed effects, and treatment dummies:

$$\text{fertility} = \beta_0 + \beta_1 T_1 + \beta_2 T_2 + \text{State FE} + \text{Year FE} + \epsilon, \quad (14)$$

where  $T_1$  is a dummy variable for being in the “partially treated” group, and  $T_2$  is a dummy variable for being in the “fully treated” group. The standard errors are clustered at the state level. Since the model prediction concerns the long-run impacts of policies, coefficient  $\beta_2$  is the one of interest. To explore heterogeneous treatment effects, I also estimate the specification in Equation (14) separately for women with or without high education, which is defined as having at least one year of college experience (see Figure B.3). Table 3 reports the regression results.

Table 3: Effects of the APFD on the Completed Fertility Rates

	(1)	(2)	(3)	Model Predictions		
	Full Sample	Low Educ.	High Educ.	Average	Low Educ.	High Educ.
$\beta_1$	0.098 (0.027)	0.216 (0.036)	0.074 (0.021)			
$\beta_2$	0.172 (0.032)	0.296 (0.041)	0.105 (0.025)	0.14	0.28	0.07
# Obs.	146,804	69,511	77,293			

*Notes:* This table reports the effects of the Alaska Permanent Fund Dividend (APFD) on the completed fertility rates. The first three columns report regression results of specification (14) using data from the Current Population Survey (CPS). Standard errors, in parentheses, are clustered at the state level. Column (1) shows the results with full sample. Column (2) shows the estimated coefficients among women without any college experience. Column (3) shows the estimated coefficients among women with at least one year of college experience. The next three columns show model predictions of changes in fertility for the average women, women with low education (30<sup>th</sup> percentile of human capital), and women with high education (70<sup>th</sup> percentile of human capital).

Column (1) of Table 3 shows that the estimated effects of the APFD on the completed fertility rates is  $\hat{\beta}_2 = 0.172$  children per woman with a 95% confidence interval of (0.109, 0.235).<sup>27</sup> The model-predicted policy effects of 0.14 children per woman is within this range. Results on  $\hat{\beta}_2$  from columns (2) and (3) also confirms the model’s prediction on heterogeneous treatment effects: women without high education responds more strongly to the APFD.<sup>28</sup> Quantitatively, these estimates are consistent with the model predictions for women with low and high education (mapped to the 30<sup>th</sup> and 70<sup>th</sup> percentiles of human capital).

<sup>27</sup>This finding echos the results in Yonzan et al. (2020). Using synthetic control methods on Natality files, they conclude that the total fertility rate in Alaska increases by 13.1% due to the APFD.

<sup>28</sup>This finding echos the results in Cowan and Douds (2021) where they find larger increases in fertility among Alaska natives and women without a high school degree.

Furthermore, the model predicts that following an increase in fertility, children will have lower human capital on average due to the quantity-quality trade-off. To assess the plausibility of this prediction, I inspect the education attainment of individuals of 25- to 30-years old in Alaska and other states by birth cohort. Figure B.4 shows that while Alaska has been following the national trend in college enrollment before the APFD, children born after the APFD have lower college attainment, consistent with the model’s predictions. One might worry that the oil industry boom in Alaska reduced the demand for skilled workers, hence the reduction in college attainment reflects both demand changes and the quantity-quality trade-off. Using 1% population data from the Census, I find that the rise in college wage premium between 1980 and 2000 is similar between Alaska and other states. Thus, changes in skill demand alone cannot explain the stagnation of college attainment presented in Figure B.4.

## 5 Counterfactuals

In this section, I use the model to evaluate family policies of different sizes in a general equilibrium where population distribution adjusts. I focus on a uniform cash reward for childbirth (i.e. baby bonuses  $\mathcal{B}$ ) for two reasons. First, the policy’s structure is simple and similar to expanding the fully refundable Child Tax Credit (CTC).<sup>29</sup> The simplicity in policy structure facilitates better exposition of the model mechanisms. Second, such cash rewards have already been widely adopted in the developed world (see Drago et al., 2011; González, 2013). I discuss the long-run implications of baby bonuses in Section 5.1 where the government balances the budget by adjusting consumption taxes. The outcome variables of interest consists of fertility, human capital, average income, intergenerational mobility (measured by the inverse of IGE), and social welfare. In Section 5.2, I compare the baby bonus with subsidized childcare and public education expenditures. Last, I study the transition path of the baby bonus and its distributional effects across generations in Section 5.3. I discuss the robustness of the results to alternative funding methods in Appendix A.6.

### 5.1 Baby Bonus: Long-run Implications

This section evaluates baby bonuses of different sizes ranging from \$0 to \$50,000 in 2010 dollars. I compute the long-run macroeconomic implications of these policies by comparing the long-

<sup>29</sup>There are two main differences between baby bonuses and the CTC. First, the CTC has an income requirement and phase-out region, whereas a baby bonus is usually not means-tested. As is discussed later, the main results are stronger when family policies target low-income households. Second, a baby bonus is a lump-sum transfer when the child is born, while the CTC is an annual transfer to parents when the child is below age 18. With borrowing constraints, low-income parents prefer baby bonuses to a CTC of the same net present value because they can replicate the latter through savings.

run steady state of the economy with the benchmark economy where the baby bonus is zero.

Figures 8a and 8b show the fertility effects and the direct fiscal costs of baby bonuses. To reach the replacement fertility level (2.1 children per family on average), the model predicts that it would require a baby bonus of \$30,000, or approximately 1.6% of GDP in the new steady-state economy. This amount is similar to the increase in the maximum benefit of the Child Tax Credit (CTC) from 2010 to 2021 in net present value, taking the American Rescue Plan Act of 2021 into account. It offsets 19% of the average cost of raising one child as estimated by the USDA. These results confirm the common perception by demographers that using financial incentives to raise fertility is not “cheap.” Under realistic magnitudes of fertility elasticities and reasonable policy scales, the effects of financial incentives provided by the government are small relative to historical changes in preferences, social norms, contraceptive technologies, and perhaps most important of all, changes in the skill premium. These results, however, suggest that using cash transfers to prevent further crashes in fertility, or even to raise the fertility rate, is feasible in practice.

Figure 8c shows that parents in the lower half of the human capital distribution (low  $h$ ) have larger fertility responses to baby bonuses than the ones with higher human capital (high  $h$ ). This is intuitive since the same level of  $\beta$  translates into a larger proportional change in the “shadow price” of children, which is composed of the opportunity costs of time  $wh$  and private education investments  $e^*(h)$ . This prediction is also consistent with the estimated fertility effects of APFD presented in Table 3. More specifically, Figure 9 presents the fraction of fertility by parents’ income decile in the benchmark economy and under a \$30,000 baby bonus. As can be seen, the profile rotates clockwise under the baby bonus and puts more weights on parents with lower income.

Figure 8d shows the quantity-quality trade-off channel discussed in Section 2.6.1. Baby bonuses reward parents for higher fertility, and parents respond by having more children, but they reduce private investment in children’s education. Average  $e$  falls by 4% when fertility reaches the replacement rate. Further, due to their larger fertility responses, parents with lower human capital reduce investment in their children’s education by more than parents with high human capital. Figure 8d also displays the model predictions when fertility is exogenous.<sup>30</sup> In that case, parents spend more on  $e$  when they receive the baby bonus as an *income transfer*, with larger increases among parents with low human capital. As can be seen, implications of family policies are qualitatively different with endogenous fertility.

Due to intergenerational transmission of human capital, heterogeneous responses in fertility induce gravitation of aggregate variables towards low-income families. Composition effects, in addition to the reductions in private investment per child, lead to a reduction of the average human

<sup>30</sup>To compute this, I do not allow parents to make endogenous fertility choices and assign the number of children that corresponds to the level observed in the data (see Figure 2). Parents still make private education investments and transfer choices as in the baseline model.

Figure 8: Long-Run Effects of Baby Bonuses

*Notes:* These figures plot macroeconomic impacts of baby bonuses of different sizes by comparing long-run steady-states under policies with the baseline steady-state economy. In Figure 8d and 8c, I plot the average responses as well as heterogeneous responses by parents' human capital levels.

capital by 2% under a \$30,000 baby bonus (see Figure 8e).<sup>31</sup> As the decrease in education investments is larger among low-income households, Figure 8f shows that the \$30,000 baby bonus also reduces intergenerational mobility by 1.6% rather than boosting it as policymakers have hoped. Due to the quantity-quality trade-off mechanism, the negative policy effects on social mobility would be even stronger if the baby bonus is exclusively given to low-income households.

Figure 8g shows that per capita output declines by 0.6% at  $B = \$30,000$ . Nevertheless, Figure 8h indicates that in the long-run steady-state, the government is able to reduce the consumption tax by 0.9%. This is a result of several forces shaping the government budget constraint in Equation (4). First, the change in human capital distribution affects tax revenues. Second, as the share of children increases, the government needs to allocate more resources to public education. Further, as the share of retired households decreases (see Figure 8i), the government is less burdened by pension payments. Quantitatively, the last effect dominates and the government is able to reduce  $\tau_c$ , which benefits agents through their household budget constraint.<sup>32</sup> This result stands in contrast with predictions under exogenous fertility (dashed line in Figure 8h) or those from models with endogenous fertility, but agents only live for two periods.

Figure 8j plots the welfare effects in consumption equivalents. I find that the average utility of new-borns under the veil of ignorance increases by 1.6% in the long-run economy when aggregate fertility reaches the replacement level. Quantitatively, the reduction of consumption taxes by 0.9% explains more than half of the welfare improvements. The rest of the welfare gain is explained by

<sup>31</sup>The 2% reduction in average human capital is smaller than that of the private investment (-4%) because public education investment  $\mathcal{E}$  is unchanged.

<sup>32</sup>I do not expect this result to change qualitatively if instead of a single fiscal budget constraint (4), the government finances the PAYG system using labor taxes and uses other taxes to finance the rest of the expenditures. In that case, a reduction of share of retirees would lower labor taxes, leaving households with higher income, consumption and savings, and utility.

Figure 9: Fertility Weights

Notes: This figure plots the fraction of childbirth by parents' income decile in the benchmark economy without baby bonus and in the counterfactual economy with a \$30,000 baby bonus.

(1) higher fertility, (2) insurance benefits *ex ante*, and (3) changes in the distribution of agents.

## 5.2 Comparing Policies: Subsidized Childcare and Education Expenditures

In this section, I highlight results from policy comparisons. For more details on subsidized childcare and public education expenditures, see Appendices C.1 and C.2.

Compared with baby bonuses, subsidized childcare is less cost-effective in raising fertility. While it takes a baby bonus equal to 1.6% of GDP to boost aggregate fertility to the replacement level, the government needs to spend 2.5% of GDP if it uses subsidized childcare to achieve the same goal (see Figure 10a). This result is consistent with evidence from historical policies (Luci-Greulich and Thévenon, 2013; Stone, 2020). It is also intuitive; compared with cash benefits, subsidized childcare offers fewer benefits per child (in consumption equivalents) to parents with low human capital (see Figure 11a) given that they would prefer to spend the money elsewhere.

Different from baby bonuses, subsidized childcare encourages the combination of childbearing and working, especially among parents with low human capital.<sup>33</sup> This in turn fosters adults' human capital accumulation via on-the-job learning. As a result, subsidized childcare leads to more

<sup>33</sup>Hours worked among parents with low human capital fall after the implementation of a baby bonus for two reasons. First, these parents are most responsive in fertility, which drives up the total childcare time. Second, due to increasing economies of scale in home production of childcare, the increase in fertility decreases the relative price of home versus market childcare. See González (2013) for empirical evidence of these predictions. As discussed in Section 2.6.4, hours worked among parents with low human capital increase under subsidized childcare as the policy “pushes” them from home production of childcare to market work if they want to benefit from the in-kind transfers.

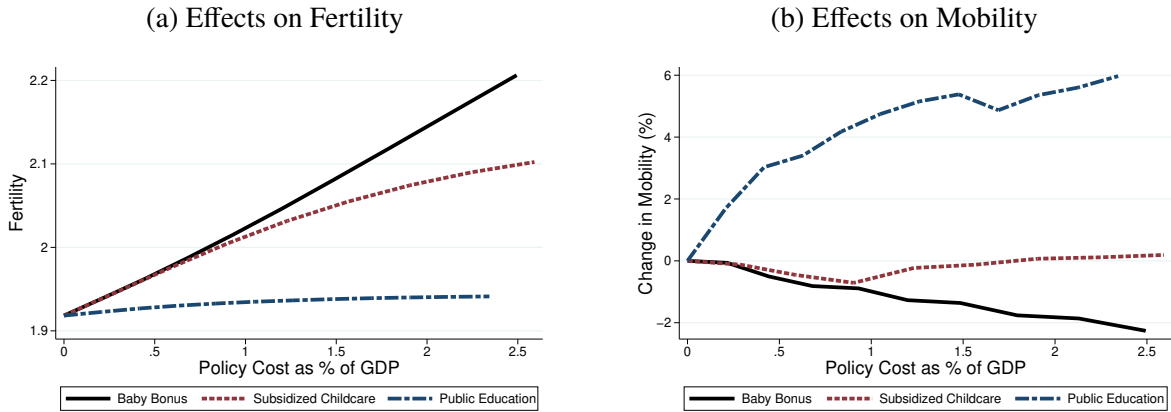

equitable income growth across agents with different initial human capital (see Figure 11b) and reduces life-cycle wage inequality.

The fertility effects of public education expenditures are an order of magnitude smaller than those from baby bonuses for two reasons. First, public education expenditures only indirectly affect quantity choices through changes in child quality. Second, in the long run, education expenditures increase the share of parents with higher human capital, who have a fewer children. Thus, the government should not expect to use education expenditures as an effective pro-natal policy instrument. While a \$30,000 baby bonus boosts aggregate fertility from 1.92 to 2.1 (the replacement level), an education expansion of the same size only raises aggregate fertility by 0.011 (see Figure 10a).

Similar to baby bonuses, private investments in children's education also fall under public education expansion, but for a different reason. Parents spend less on children's education under an expansion of public education expenditure due to crowding-out effects. This is because public and private monetary inputs into child human capital formation are substitutes.

Despite mild fertility effects, expanding public education is the most effective policy among those evaluated at raising social mobility and improving children's outcomes. Figure 10b indicates that different from baby bonus or subsidized childcare, an expansion of public education that is 1.5% of GDP raises intergenerational mobility by 5.2%.<sup>34</sup> This effect will be larger if the public education expenditure is targeted at low-income households.

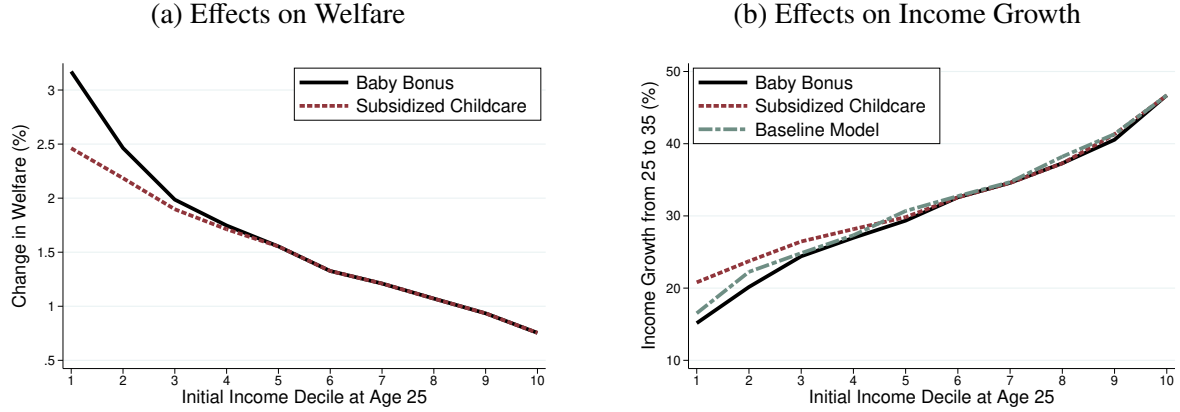

Figure 10: Compare Policies: Effects on Fertility and Mobility

Notes: This figure compares baby bonus  $\mathcal{B}$  with subsidized childcare  $\mathcal{S}$  and public education  $\mathcal{E}$  on the basis of effects on fertility and intergenerational mobility.

<sup>34</sup>These values are smaller than the projected policy effects by Daruich (2018) as Daruich (2018) does not consider endogenous fertility which dampens the policy effects on child quality through the quantity-quality trade-off.

Figure 11: Baby Bonuses and Subsidized Childcare: Effects on Welfare and Income Growth

Notes: This figure compares baby bonus  $B$  with subsidized childcare  $S$ . The direct expenditure on each policy is 1.6% of GDP in the long-run steady-state.

### 5.3 Baby Bonus: Transition Path

In this section, I discuss the transition path results following the implementation of a \$30,000 baby bonus that leads to the replacement level fertility rate in the long run. The policy is enacted unexpectedly at period  $t = 1$  and stays in place for all subsequent periods. The government changes consumption taxes along the transition path to balance the budget in each ten-year period.<sup>35</sup>

Figure 12a shows that the policy effects on fertility are immediate and persistent. Figure 12b indicates that the old-age dependency ratio starts to decline in period 6, given that past fertility rates predetermine the ratio of the retired to working-age population in the short run. The total dependency ratio, however, increases immediately after the policy is adopted due to a large increase in the number of children born due to the baby bonus.

As a result of this increase in the total dependency ratio, the government needs to finance additional expenditures in the first few periods. Such expenditures include education and transfers to parents with children through the tax system. These “induced” expenditures make the overall costs of family policies much larger than the direct expenditures.<sup>36</sup>

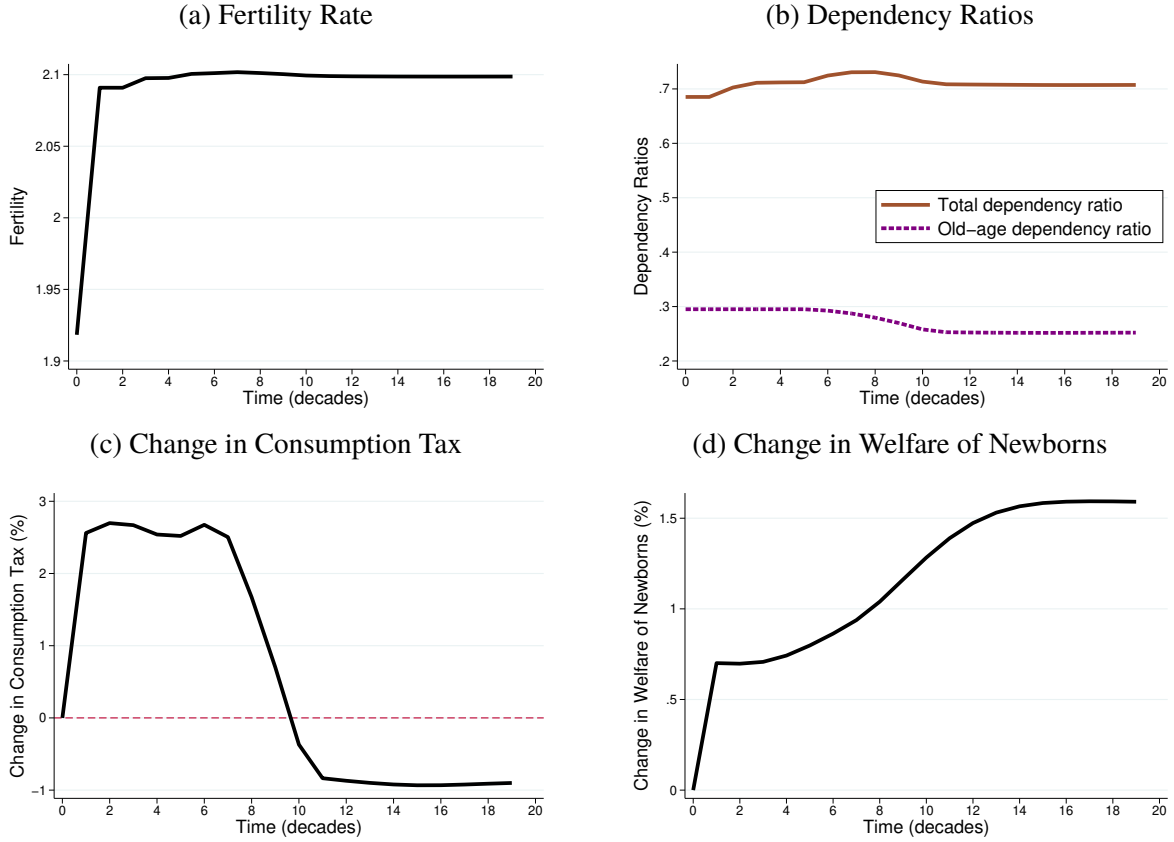

In the baseline model, the government balances the budget period by period using consumption taxes. As a result, Figure 12c shows that consumption taxes rise at first before falling in the long run. Hence, welfare changes of new-born agents in transition are positive but significantly smaller

<sup>35</sup>I discuss an alternative way of using government borrowings to fund fiscal expenditures in Appendix A.6. Furthermore, finding the optimal transition is interesting but rarely implemented in quantitative models since the dimensionality of policy instruments is immense. One notable exception is Bakış et al. (2015) where they compute the optimal path of taxes along the transition path in a stylized Aiyagari-Bewley-Huggett model. This would be interesting in my richer model but is beyond the scope of this paper.

<sup>36</sup>For example, while the direct cost of a \$30,000 baby bonus is 1.6% of GDP, the government needs to raise consumption taxes by 2.6% for the first seven decades of the transition.

than those in the long-run steady state (see Figure 12d). Most existing agents in the economy at  $t = 1$  do not benefit from the baby bonus, but they are still required to pay higher consumption taxes, leaving them worse off.

Figure 12: Transition Path of a \$30,000 Baby Bonus

*Notes:* These figures plot the evolution of aggregate variables under a baby bonus of \$30,000. Each period represents 10 years. The policy is enacted at period 1.

The transition path results shed light on two insights that hold more generally beyond the case of a baby bonus. First, the overall fiscal burden induced by family policies is usually much higher than the policy expenditure itself, especially in the first few decades in the transition path. When more children are born, the government needs to finance additional expenditures for existing child-related policies. The potential fiscal benefits of reductions in the old-age dependency ratio, on the other hand, will be realized much later than the upfront costs. Second, the amount of political support for family policies depends on how the fiscal costs are distributed across generations. The government will have a hard time gathering enough agents to support family policies that benefit the economy in the long run at the cost of existing households. In that sense, family policies are similar to climate change mitigation policies where countries wait “too long” to act due to frictions

caused by intergenerational public finance (Sachs, 2014).

## 6 Optimal Policy

In this section, I study the optimal baby bonus to address the externalities of childbearing and inefficiencies caused by borrowing constraints. I begin with a discussion of welfare criteria under heterogeneous agents and endogenous fertility. Then, I show optimal policy results and propose principles for designing family policies in general.

### 6.1 Welfare Criteria

Welfare criteria in models with endogenous fertility are complicated both conceptually and philosophically. Unlike standard comparisons between allocations where the set of agents is fixed, in this context there will be agents born in one economy but not in the other. As a result, the standard Pareto principle cannot be used to conduct welfare analysis in this context. The field of population ethics is devoted to understanding and resolving this question.<sup>37</sup>

As the debate on welfare criteria is far from being settled, I adopt two definitions in studying the optimal policy. The first criterion is the *long-run average welfare*  $\mathcal{W}$  used in previous sections. It evaluates the expected utility of a newborn child in the long-run stationary equilibrium under the veil of ignorance. The second criterion assesses the *average utility of existing agents* when the policy is adopted.<sup>38</sup> I decompose this into welfare changes for existing parents ( $j = 2$ ) who receive the baby bonus and for other households ( $j > 2$ ) who are not direct beneficiaries of the policy. The latter criterion has two features. First, it is forward-looking, as it incorporates tax changes in later periods that affect these households' utility. Second, with this criterion, the unique solution to the planning problem corresponds to the notion of  $\mathcal{A}$ -efficiency defined in Golosov et al. (2007) which focuses on the welfare of those already alive.

Rather than computing the unconstrained optimum, I follow the Ramsey tradition and allow the government/planner to use only a certain policy instrument (a baby bonus) that is uniform across households and birth order. As in previous sections, I consider the scenario where the government

<sup>37</sup>For instance, Parfit (1984) derives the famous “repugnant conclusion” showing that under a set of intuitively appealing assumptions, one can prove “for any perfectly equal population with very high positive welfare, there is a population with very low positive welfare which is better, other things being equal.” Golosov et al. (2007) propose two criteria called  $\mathcal{A}$ -efficiency and  $\mathcal{P}$ -efficiency which differ by whether the planner evaluates the welfare of those who are not born. De la Croix and Doepke (2021) consider the optimal welfare from a soul's perspective where one needs to consider both the utility of being born and the average “waiting time” for incarnation.

<sup>38</sup>Following standard practice in quantitative macroeconomic literature, I use equal weights as a benchmark. Another approach is to use the Negishi weights, which put a greater weight on households with higher human capital and initial assets. This would eliminate the redistributive benefits of baby bonuses. See Kim et al. (2021) for an example.

adopts the baby bonus at the beginning of time period  $t = 1$ . The policy change is permanent and financed by consumption tax changes. I use  $\mathcal{B}_{lr}^*$  to denote the optimal baby bonus that maximizes average utility in the long run, and I use  $\mathcal{B}_{sr}^*$  to denote the optimal baby bonus that maximizes the average utility of existing households when the policy is adopted.

## 6.2 Optimal Policy Results

Figure 13 shows the changes in welfare under different baby bonuses for two welfare criteria. From a long-run perspective, the optimal baby bonus is  $\mathcal{B}_{lr}^* = \$60,000$ .  $\mathcal{B}_{lr}^*$  boosts aggregate fertility to 2.4 children per woman, raises long-run welfare by 2%, and costs around 4.1% of GDP.

The baby bonus that maximizes the welfare of the median voter among existing households, however, is  $\mathcal{B}_{sr}^* = \$0$ . Current parents who receive the baby bonus prefer larger  $\mathcal{B}$  for two reasons. First, despite the higher taxes in transition, these households are subsidized by older households ( $j > 2$ ) on net. Second, the baby bonus redistributes towards poorer parents, which improves average welfare. Older households in the economy, however, oppose the baby bonus because they do not benefit from the bonus but still pay higher taxes for the remainder of their lives. If each household has the same voting power, then  $\mathcal{B}_{sr}^* = \$0$  is the most likely outcome from a political perspective. As discussed in Section 5.3, this observation explains the observed puzzle where many countries with extremely low fertility rates fail to implement large-scale family policies despite knowing the dire consequences in the long run. Even when they do implement these policies, governments often renege on the promises due to fiscal pressures. For example, the Australian baby bonus was significantly downsized in 2014.

## 6.3 Discussion

Even though this paper restricts the study of optimal policy to choosing the optimal level of a baby bonus, it highlights the major trade-offs in policy design that are broadly applicable to other instruments and goals.<sup>39</sup> On the one hand, subsidizing childbirth among parents with low human capital leads to larger fertility changes per dollar spent on family policies. This in turn leads to larger welfare improvements due to changes in the demographic structure. On the other hand, subsidizing childbirth among parents with high human capital improves the equilibrium human capital distribution via intergenerational transmission of skills, thereby raising welfare due to composition effects. At the aggregate level, the government balances population growth, average human capital,

<sup>39</sup>For instance, it is straightforward to incorporate subsidized childcare and public education expenditures, shown in Appendices C.1 and C.2. Instead of choosing a permanent policy change to the baby bonus, one could also conduct dynamic optimal policy design where the size of the bonus varies over time.

Figure 13: Optimal Baby Bonus by Welfare Measure

*Notes:* This figure plots the changes in welfare under baby bonuses of different sizes. I consider two welfare criteria: (1) average utility of a new-born child in the long run and (2) average utility of existing households when the policy is enacted, decomposed into agents who receive the baby bonus and agents who do not receive it.

and distortions through the taxation by weighing the quantity-quality trade-off, composition effects, demographic structure effects, and changes in childcare arrangements.

With countervailing forces present in the unified model, the first-order stochastic dominance (FSD) in equilibrium human capital distribution is neither necessary nor sufficient for choosing better policies. For instance, the equilibrium human capital distribution under a \$30,000 baby bonus is first-order stochastically dominated by that in the baseline economy, but average well-being improves in the long run. The key insight is that besides comparing human capital distributions across economies, one also needs to consider differences in the *age distribution*. Thus, this paper provides a novel counterargument to the common conclusion in the existing literature on family policies arguing for childbirth restrictions among parents with low human capital (e.g., [Chu and Koo, 1990](#)). These parents, with higher fertility responses to per dollar benefit, could be key to solving population aging problems.

## 7 Conclusion

Facing aging populations, family policies have been widely pursued to encourage childbirth. On the other hand, evidence of the effects of transfers to parents on children's outcomes lead policymakers and economists alike to believe that family policies are good instruments to "lift children out of poverty today and help them tomorrow" ([Schanzenbach et al., 2021](#)).

In this paper, I study the aggregate impacts of family policies in a heterogeneous agent overlapping generations model. Relative to previous studies on family policies, this paper is the first to combine the quantity-quality trade-off, an endogenous demographic structure, and childcare choices in a quantitative macroeconomic framework. I argue that fertility elasticities are the key moments disciplining a number of mechanisms in models featuring endogenous fertility choices, and this class of models would benefit greatly by incorporating estimates from the empirical literature.

In the calibrated model, I find that when governments design family policies that reward having more children, parents respond by increasing child quantity but optimally reduce child quality. Compared with education subsidies, child benefits are not ideal instruments if the government aims to raise child human capital or boost social mobility. However, the pro-natal effect of family policies could lead to long-run welfare gains: lower old-age dependency ratio allows the government to cut taxes. I also show that the long-run gains in welfare require a transition path where the government needs to finance higher child-related expenditures during the first few decades. Depending on how the government decides to finance these higher costs, the welfare of existing households could fall.

The tractability of the model allows for several extensions and applications, which are left for future research. First, one can calibrate the model to match the institutional details of other countries and conduct policy counterfactuals on a case-by-case basis. Moreover, it would be interesting to consider the optimal policy design with additional or jointly-used policy instruments under different welfare criteria. For instance, when the government uses a baby bonus to raise fertility, it could expand public education at the same time to offset the reduction in private education investments due to the child quantity-quality trade-off.

Bold entries report maximum (of absolute value) by row, highlighting the moment that is most sensitive to parameter changes. See Table 2 for definitions of parameters and identifying moments.

## A.2 Alternative Preferences

There are alternative ways to model parents’ preferences over child quantity and quality. I argue that the modeling choice in Section 3.1 results in a conservative benchmark relative to other parameterizations.

Separable preferences between quality and quantity (see [de La Croix and Doepke, 2003](#); [Bar et al., 2018](#); [Vogl, 2016](#)) is a commonly-used assumption where

$$v(n, \mathbb{E}h_k, a_k) = \log(n) + \theta \log(\mathbb{E}h_k) + \nu \log(a_k).$$

Compared with our benchmark case where quality and quantity are complements, parents will raise fertility and reduce child quality even more strongly when the government rewards childbirth. This is because the interaction in preferences  $v(n, \mathbb{E}h_k, a_k)$  is not present when quantity and quality are separable. I show this result with closed-form solutions in Appendix E.1. For the same reason, if quantity and quality are substitutes, the results in this paper will be conservative ([Jones and Schoonbroodt, 2010](#)).

Another way of modeling parents’ preferences is with dynastic altruism (see [Córdoba et al., 2016](#); [Daruich and Kozlowski, 2020](#)) where

$$v(n, \mathbb{E}h_k, a_k) = \Psi(n)V_2(\mathbb{E}h_k, a_k).$$

This formulation is similar to the one used in this paper with the exception that utilities from child quality are pinned down recursively. Dynastic altruism is appealing from an efficiency point of view ([Golosov et al. \(2007\)](#)), but whether such models could fit observed transfers between parents and children is still being debated (see [Altonji et al., 1997](#); [Barczyk and Kredler, 2020](#)). Paternalistic motives are often added to improve data fit (e.g., [Abbott et al., 2019](#)).

In this paper, I adopt warm-glow utilities rather than dynastic altruism mainly for computational tractability. Nevertheless, the results will also be stronger under dynastic altruism: parents endogenize the fact that returns to child quality become lower when the government creates a “social safety net” for children with low human capital by providing generous family benefits. As a result, parents would further increase child quantity and reduce quality investments. For instance, [Daruich and Fernández \(2020\)](#) argue that universal basic income reduces the human capital of future generations due to this mechanism.

## A.3 Endogenous Timing of Childbirth

In the baseline model, I abstract away from birth timing by assuming that parents only make fertility choices from age 20 to 30. In reality, parents can decide when to give birth, and family

policies could affect that decision. This is known as the *tempo effects* of family policies.<sup>40</sup>

I argue that adding endogenous timing will make my baseline results stronger. As the model matches effects on the completed fertility rate (known as the *quantum effects*) in the validation exercise, policy effects on the total fertility rate (quantum plus tempo) will be larger. Suppose that in addition to increasing the number of children, some parents shift birth from their 30s to their 20s in response to a baby bonus. This shift in birth timing will likely be detrimental to child human capital for two reasons. First, early birth reduces the spillover that the children could receive because parents' human capital grows rapidly from age 20 to 40. Second, family policies of realistic sizes fall short of offsetting the income differences of parents between early and late births. Hence, these children are born into households with fewer resources on average, which would also reduce child human capital as investment falls. As a result, family policies will have a larger observed fertility impact on the economy with endogenous timing of birth, but the outcomes of children will be even worse.

## A.4 Bequests

The model restricts the set of timings that parents could make transfers to children to  $j = 3$ . I make this simplifying assumption to keep the model tractable – if parents can leave end-of-life bequests to their children, then children need to keep track of parents' state space, including human capital and assets.

I argue that this simplification does not significantly affect my model results. Because the key mechanisms of the model (i.e., quantity-quality trade-off and childcare choices) occur in period  $j \in \{2, 3\}$ , the possibility of receiving a bequest at  $j \in \{5, 6\}$  does not matter for households' choices if they cannot borrow against it due to life-cycle credit constraints. In the calibrated model, most households, especially those with low human capital who are most responsive to family policies, hold few assets in the beginning of their life cycles despite receiving the inter vivos transfers from their parents (see Figure 3).

## A.5 Alternative Measure of Fertility

As the baseline model focuses on the total number of children that parents decide to have, the most appropriate measure of fertility in this context is the completed fertility rate (CFR), measured using data on either “children ever born” in Census data (dropped after 1990) or “live births ever

<sup>40</sup>An unresolved question is whether changes in timing are due to the relaxation of parents' constraints (e.g., down payments to buy a larger house) or the lack of commitment to policies by the government. Historically, governments often renege on family policies as fiscal conditions change. The significant downsizing of the Australian baby bonus in 2014 is one good example. This uncertainty creates an incentive for parents to shift birth timing while benefits are still in effect.

had” in the CPS June Fertility Supplement. As discussed in Section 4, the CFR has the advantage of being invariant to shifts in birth timing due to policy changes. For these reasons, in Figure 5.2 and the calibration, I use the CFR by household income decile, calculated using the sample of married women age 40-55 in the 2008-2014 CPS Fertility Supplement.<sup>41</sup>

One disadvantage of using the CFR is that these women made their fertility decisions prior to 2010 where they may have faced different trade-offs. The total fertility rate (TFR) is an alternative measure that is more responsive to contemporaneous situations, calculated by summing the age-specific birth rates of all women alive in a given year. This measure is simple to compute and widely used in the literature (Kremer and Chen, 2002).

TFR by income decile, however, is less straightforward to compute than CFR by income decile. First, one does not want to assign income ranks that mix young women with older women due to life-cycle changes in the earnings profile. Second, given that the appropriate measure of income is total family income, one would not want to mix married women with single women. Daruich and Kozlowski (2020) provide a recent estimate of TFR by income decile using data from the 2000 Census. They restrict the sample to married women between ages 15-49 who are either themselves household heads or spouses of the household head. Income deciles are assigned by comparing the total family income of each woman with other observations in the same age group. To alleviate selection bias into marriage for younger age groups, they also drop age-income groups with a small number of observations. For each income decile, they calculate the TFR by adding up the age-specific fertility rates in that decile. Figure A.1 shows that their result is quantitatively similar to the CFR estimates used in the calibration.

## A.6 Alternative Financing Methods

In the baseline policy counterfactual and the optimal policy analysis, the government changes consumption taxes  $\tau_c$  to balance the budget in every period. This assumption is made primarily for computational reasons.

I argue that my results on human capital and social mobility are unlikely to change when the government can borrow from domestic or international lenders. In particular, all of the main policy mechanisms (i.e., quantity-quality trade-off, composition effects, changes in demographic structure, and adjustments in childcare arrangements) are independent of whether or not the government is

<sup>41</sup>In a steady-state economy, fertility choices across cohorts are stationary, and hence the CFR coincides with the total fertility rate (TFR). For this reason, I normalize the CFR target in the calibration of  $\psi$  to match the total fertility rate in 2010, which was 1.92 children per woman. Model results are quantitatively similar if I omit this step. I have also experimented with a version of the model where a fraction of adults remain single and (exogenously) childless, meaning that the CFR in the economy is a weighted average between single adults without children and married households whose within-group CFR is higher than 1.92. The overall results are again similar.

Figure A.1: Fertility Rate by Income Decile

Notes: This figure plots the total fertility rate by income decile measured in [Daruich and Kozlowski \(2020\)](#) and the completed fertility rate used in model calibration.

allowed to borrow. As a result, I expect the model predictions on fertility, human capital, output, and mobility to be unchanged in a model with government borrowing.

Welfare implications, however, will likely change depending on how government expenditures are funded. For example, since the \$30,000 baby bonus generates welfare improvements for all agents in the long run, it is natural for the government to shift the fiscal burden to these beneficiaries via borrowing instead of asking existing elderly households to fund additional expenditures from which they derive little benefit (see Figure 13). If the government chooses to do so, then the welfare effect in the long-run economy will be smaller, while the effect on existing agents will be less negative. Such a policy change is also more likely to gain sufficient political support for implementation as it does not directly hurt existing agents who have voting power. On the other hand, if the government issues debt to finance large-scale family policies, the overall borrowing cost for the government could increase in general equilibrium if lenders require higher compensation for a larger debt-to-GDP ratio. This might crowd out other government borrowing that benefits existing households. As a result, whether current agents prefer government borrowing or changes in taxation also depends on the opportunity costs of family policies.

Despite the intuitive appeal of using government deficits to finance large-scale family policies that benefit future generations, family policies are often financed by adjusting fiscal revenues and expenditures in current policy proposals. For example, the American Families Plan vows to increase the tax rates among the very rich, while the Family Security Act proposed by Senator Romney would reform and consolidate outmoded federal programs. If the government chooses to finance family policies by changing capital or labor taxes, it could lead to additional distortions in this economy by

affecting the accumulation of physical and human capital. But given that the present paper focuses on the direct effects of family policies rather than capital or labor taxation, I do not explore how different financing methods affect the economy being studied.

## B Additional Figures on the APFD

Figure B.2: APFD and Completed Fertility Rate

*Notes:* This figure plots the average completed fertility rates for women aged 40-55 by state of residence from 1982 to 2018 using data from the CPS Fertility Supplement combined into 8-year bins. Bars around sample means show 90% confidence intervals.

Figure B.3: APFD and Completed Fertility Rate by Education

*Notes:* This figure plots the average completed fertility rates for women aged 40-55 by state of residence and education from 1982 to 2018 using data from the CPS Fertility Supplement combined into 6-year bins. I define women with high education as those who have at least one year of college experience. Bars around sample means show 90% confidence intervals.

Figure B.4: APFD and College Attainment by Cohort

*Notes:* This figure plots the fraction of 25- to 30-year-olds with at least one year of college experience by birth cohort by state of residence using data from the CPS combined into 5-year bins. Bars around sample means show 90% confidence intervals.

## C Additional Results

### C.1 Public Childcare

In this section, I evaluate childcare subsidies where the government offers  $\mathcal{S} \in [0, 0.9 \cdot \chi]$  market childcare services for all families, equivalent to 0 to 36 hours of public childcare per week.

I find that subsidized childcare raises fertility, but at a higher cost than baby bonuses. The government needs to provide 25 hours of subsidized childcare to raise the aggregate fertility rate to 2.1. This would cost almost 2.5% of aggregate GDP in the long-run steady-state economy, which is 0.8 percentage point higher than a baby bonus that achieves the same fertility goal.

Figure C.5d shows that similar to the baby bonus counterfactual, parents reduce private education investments due to the quantity-quality trade-off. Figure C.5c shows that fertility responses are higher among low-income parents. Due to reductions in private investment and composition effects, average human capital in the economy decreases (see Figure C.5e). The overall effects on intergenerational mobility are small (see Figure C.5f).<sup>42</sup>

Figure C.5g shows that output per capita increases with subsidized childcare. Compared with the baby bonus, the output changes are larger for three reasons. First, composition effects are milder because the fertility differentials between parents with low and high human capital are smaller than those under the baby bonus (see Figure C.5c). Second, the childcare subsidy raises the labor supply by replacing home care with subsidized market childcare. Finally, the increased working time during age 20-30 translates to high human capital for adults in later periods due to learning-by-doing in the labor market. Relative to the original steady-state, Figure C.5i shows that the government can reduce consumption taxes by 0.6%. Long-run welfare could be raised by 2.5% when aggregate fertility is around the replacement level.

Figure C.5: Long-Run Effects of Childcare Subsidies

<sup>42</sup>The effects on mobility are not monotonic because besides changing child human capital, subsidized childcare also changes hours worked, affecting household earnings.

(c) Heterogeneous Fertility Response

(e) Average Human Capital

(f) Intergenerational Mobility

(g) Per Capita Output

(h) Demographic Structure

(i) Change in Consumption Tax

(j) Change in Welfare

Notes: These figures plot macroeconomic impacts of childcare subsidies of by comparing long-run steady-states under different policies to the baseline steady-state economy.

## C.2 Public Education

In this section, I evaluate expansions of public education expenditures from the current level of \$12,000 per student per year. The size of the increment varies between \$0 and \$100,000 in net present value. Figure C.6a shows that the effect on fertility is positive: as public education raises children's human capital, they become more desirable to parents. The magnitude of the fertility effect here is much smaller than that of family policies. Compared with a \$30,000 baby bonus that raises fertility by 0.2 children per woman, an education expansion with costs being the same share of GDP only raises fertility by 0.011. The government should therefore not expect to use education policies to raise aggregate fertility to the replacement level.

Figure C.6c shows that the fertility response is larger for households with higher human capital. An increase in public education expenditure also crowds out private input (see Figure C.6d). Due to strong crowding-out effects, average human capital only increases by 2.5% when the education expansion exceeds \$80,000 in net present value. It is costly to raise average human capital in the economy using uniform policies in general equilibrium because (1) crowding-out effects are strong and (2) investments face decreasing marginal returns as  $\mathcal{E}$  is already \$12,000 per year in the baseline economy.

Expanding public education, however, most effectively raises social mobility. As the expansion exceeds \$60,000 in net present value, intergenerational mobility rises by almost 5.2%. If the policy targets lower-income households, one can expect larger effects on mobility. Due to increased human capital, public education expansion of \$60,000 raises output by 2.3%. The government needs to increase the consumption tax by 0.75% to finance such expenditures. Figure C.6j shows that welfare could be increased by up to 2.5%.

Figure C.6: Long-Run Effects of Public Education Expansions

(c) Heterogeneous Fertility Response

(d) Heterogeneous Private Input Response

(e) Average Human Capital

(f) Intergenerational Mobility

(g) Per Capita Output

(h) Demographic Structure

(i) Change in Consumption Tax

(j) Change in Welfare

Notes: These figures plot macroeconomic impacts of expansions of public education expenditures by comparing long-run steady-states under policies to the baseline steady-state economy.

## D Additional Validating Evidence

### D.1 Australian Baby Bonus

This section compares the implications of the calibrated model with the empirical evidence from a recently adopted baby bonus in Australia.

The Australian government announced the introduction of a universal cash payment, i.e., a baby bonus, in its federal budget on May 12, 2004. It was designed to be a non-means-tested and non-taxable lump-sum payment of AU\$3,000 to encourage childbirth. The transfer would be paid to parents following the birth or the adoption of a child up to 2 years of age after July 1, 2004. Such payments were independent of family income, maternal employment status, or the number of existing children in the household. The payment amount was equivalent to 4 times the weekly average earnings in Australia, or \$2,800 in 2010 U.S. dollars.

[Drago et al. \(2011\)](#) conduct a comprehensive analysis of the fertility effects of the Australian baby bonus using household panel data ( $N = 14,932$ ) from the Household, Income and Labour Dynamics in Australia Survey (HILDA) and a simultaneous equations approach. They first estimate the effect of the baby bonus on households' birth intentions in a linear regression, which, in turn, predicts actual births in a binomial probit regression. They exploit the panel structure of the data to test and correct for announcement effects, compression/tempo effects, and delayed effects. Regression results show that the baby bonus has significant and positive impacts on fertility. Moreover, the fertility responses are concentrated among low-income women.<sup>43</sup> [Risse \(2010\)](#) reports similar findings on women's birth intentions.

When I compare these empirical studies to the model, both the finding on the overall fertility effect and the heterogeneities across households are consistent with predictions in Section 5.1. [Drago et al. \(2011\)](#) estimate that the marginal cost to the government of an additional birth is at least A\$126,000, roughly 4 times the GDP per capita in 2004 Australia dollars. The calibrated model generates a quantitatively similar conclusion where the marginal costs for an additional birth using a US baby bonuses in 2010 are around 3.5 times the GDP per capita.<sup>44</sup>

[Gaitz and Schurer \(2017\)](#) evaluate the effect of the Australian baby bonus on child human capital accumulation using high-quality panel data from the Kindergarten cohort (K-cohort) of the Longitudinal Study of Australian Children (LSAC). They find that the baby bonus, despite being

<sup>43</sup>This finding is different from that of [Milligan \(2005\)](#) where the author evaluates a child benefit in Quebec and finds larger responses among parents with higher incomes. [Drago et al. \(2011\)](#) propose that the difference could be due to the fact that the Quebec baby bonus was significantly more generous for high-parity births. [Milligan \(2005\)](#) discusses some other possible explanations such as unobserved heterogeneities that are systematically related to income.

<sup>44</sup>To provide additional corroborative evidence, leveraging a large-scale subsidy called Maternity Capital, [Sorvachev and Yakovlev \(2019\)](#) find that the costs of an additional birth in Russia is approximately \$50,000, around 3.5 times the GDP per capita of Russia in 2011.

significant in size, is not effective in boosting learning, socio-emotional or physical health outcomes of the average pre-school child. This finding is consistent with results in Section 5.1 where parents optimally reduce private education investments due to the quantity-quality trade-off.

## D.2 Spanish Child Benefits

In this section, I provide additional evidence of the fertility effects of child benefits using a universal child benefits policy in Spain.

The Spanish government announced the new child benefit on July 3, 2007. The benefit was a one-time payment of €2,500 to the mother immediately following a child's birth on and after July 1, 2007. Since the cash benefit was universal and independent of the recipient's characteristics, it was essentially a universal baby bonus (c.f., the Australian baby bonus, and  $\mathcal{B}$  in the model). The size of the payment is 4.5 times the monthly gross minimum wage for a full-time worker or \$3,500 in 2010 U.S. dollars.

González (2013) studies the effect of the Spanish child benefit on fertility and mothers' labor supply using monthly vital statistics, monthly abortion statistics, and the 2008 Household Budget Survey ( $N = 958$ ). In the paper, fertility effects are assessed by inspecting the time series of births and abortions, while effects on the labor supply are estimated using a regression-discontinuity design by comparing households who gave birth right before and right after the cutoff date. González (2013) finds that the fertility effects are positive and significant, with the policy increasing the total fertility rate by 6%. Around 80% of this increase is due to increased conception while the remaining 20% is due to reductions in abortion. The result suggests that (in Spain) the marginal cost of an additional birth using baby bonuses is 3.6 times the GDP per capita.<sup>45</sup> The model counterpart to this statistic is 3.5.

González (2013) also finds that the baby bonus reduced mothers' labor force participation. The calibrated model produces this effect via two channels. First, as the baby bonus raises fertility, parents need to generate more childcare services, increasing their time at home *ceteris paribus*. Second, higher fertility reduces the relative cost of home versus market care due to economies of scale in home production of childcare ( $\iota < 1$ ). Therefore, the model predicts that parents optimally change their childcare arrangements so that their children spend less time in market care. González (2013) confirms this prediction by showing that Spanish parents reduce enrollment in formal childcare after the baby bonus.

<sup>45</sup>Summarizing historical studies with both short-run and long-run effects on fertility, Stone (2020) show that one can multiply the policy effects on total fertility rates by 1/3 to derive a crude estimate of the effects on completed fertility rates.

### D.3 Russian Maternal Capital

In this section, I provide additional evidence of the fertility effects of child benefits using a series of subsidies, called Maternity Capital, in Russia.

The Russian government introduced a sizable conditional child-subsidy program (called Maternity Capital) to address the decade-long decrease in fertility and depopulation. The program was implemented in two waves. In the first wave in 2007, the federal Maternity Capital program, a family that already had at least one child and gave birth to another became eligible for a one-time subsidy of approximately \$10,000 U.S. dollars. This figure was larger than the country's average 18-month wage or the sum of the minimum wage over a 10-year period. At the end of 2011, Russian regional governments introduced regional Maternity Capital programs that gave additional money on the top of the federal subsidy to all families with newborn children.

Using a regression-discontinuity design surrounding the program announcement date, [Sorvachev and Yakovlev \(2019\)](#) find that the program have significantly increased fertility both in the short-run and in the long-run. They estimate that the cost for an additional birth is around \$50,000, approximately 3.5 times the GDP per capita of Russia in 2011. Moreover, they find that the treatment effect is heterogeneous: while all educational groups are affected by the program, the increase in fertility is higher among low-educated mothers. In another work, [Slonimczyk and Yurko \(2014\)](#) build and estimate a structural dynamic programming model of fertility and labor force participation to evaluate the policy effects. They find that the program increased long-run fertility by about 0.15 children per women. This estimate suggest that the cost for an additional birth is around 4.6 times the GDP per capita, slightly higher than that in [Sorvachev and Yakovlev \(2019\)](#). They also find that the program “seems to have more strongly affected relatively underprivileged women”.

Subject to the caveat of not re-calibrating the model to match institutional details in Russia, these findings in both papers are consistent with the model's prediction. In particular, the model predicts that an additional birth requires a payment that is 3.5 times the national GDP per capita. Moreover, fertility responses are larger among parents with lower human capital (see Section 5.1).

## E Illustrative Models

### E.1 Simple Model of Quantity-Quality Trade-Off

In this section, I show the quantity-quality trade-off mechanism with closed-form solutions in a model that is adapted from [de La Croix and Doepke \(2003\)](#).

Agents in the economy live for two periods, child and adult. Adult parents solve the problem:

$$\max_{c,n,e} \log(c) + \theta \log(n \cdot h_k)$$

subject to

$$c + n \cdot e = 1 - n \cdot \chi, \text{ and}$$

$$h_k = e^\gamma, \quad \gamma \in (0, 1).$$

where  $c$  is consumption,  $n$  is fertility,  $h_k$  is human capital of children,  $e$  is private investment,<sup>46</sup> and  $\chi$  is fixed cost per child.

When fertility is exogenous, i.e.,  $n$  is given, parents maximize over  $c$  and  $e$ . The optimal investment is given by

$$e^* = \frac{\theta\gamma}{1 + \theta\gamma} \times \frac{1 - n\chi}{n}.$$

When the child cost  $\chi$  decreases,  $e^*$  increases due to the income effect.

When fertility is endogenous, parents maximize over  $c$ ,  $e$ , and  $n$ . The optimal fertility and investment decisions are given by

$$n^* = \frac{1}{\chi} \cdot \frac{\theta(1 - \gamma)}{1 + \theta}, \quad \text{and} \quad e^* = \frac{\gamma\chi}{1 - \gamma}.$$

When the cost of a child  $\chi$  decreases,  $n^*$  increases while  $e^*$  decreases. The intuition for this result is simple. Parents increase fertility due to the substitution effect. The increase in  $n^*$ , in turn, raises the shadow price of investment  $e^*$  due to the interaction between  $n$  and  $e$  in the budget constraint. As a result, the optimal investment  $e^*$  falls.

Compared with the benchmark model where  $n$  and  $h_k$  are complements in parents' preferences, reductions in  $e^*$  in response to a change in  $\chi$  are higher in this simple model. This is because the marginal utility in child quality  $h_k$  is independent of fertility  $n$ .

<sup>46</sup>In [de La Croix and Doepke \(2003\)](#), children receive human capital endowments. This generates non-homotheticity over child quality for heterogeneous parents with different human capital and leads to a negative income-fertility relationship. I abstract away from steady-state heterogeneity across households in this simple model for clearer exposition of intuition in comparative statics, but all arguments carry through when human capital endowments are allowed.

## E.2 Simple Model of Fertility Elasticity

In this section, I build a simple model to illustrate the relationship between the parameter  $\gamma$ , which determines the intergenerational elasticity of substitution (EGS), i.e.,  $1/\gamma$ , and the magnitude of fertility responses to family policies.

Consider a simplified problem for parents with very low income so that child quality is generated by public investments alone:

$$\begin{aligned} \max_{c,n} \quad & u(c) + \Psi(n)u(\mathcal{E}) \\ \text{subject to} \quad & c + n \cdot \chi = 1. \end{aligned}$$

The first-order condition for  $n$  is therefore:

$$\underbrace{\Psi'(n) \cdot u(\mathcal{E})}_{\text{MB of } n} = \underbrace{u'(c) \cdot \chi}_{\text{MC of } n}.$$

By substituting in  $u(c) = \frac{c^{1-\gamma}}{1-\gamma}$ , I have

$$\Psi'(n) \cdot u(\mathcal{E}) = c^{-\gamma} \cdot \chi.$$

When the “price” of child  $\chi$  falls, both  $n$  and  $c$  will rise. A higher  $\gamma$  results in a faster decay of the marginal utility change from rising consumption. To balance the first-order condition, the rise in  $n$  on the left-hand-side needs to be larger. In other words, higher  $\gamma$  leads to a greater elasticity of  $n$  with respect to changes in  $\chi$ .

This argument holds equally for  $\{\mathbb{E}h_k, a_k\}$  in the main model because they are also evaluated by parents through utility function  $u(\cdot)$ . [Soares \(2005\)](#) uses a similar argument in the context of mortality reductions of children.
